Because of the public nature of schools, political controversy may surround school-based health services, especially those related to reproductive health care. For example, for sexually active adolescents, many health care professionals consider the consistent use of condoms as an important preventive measure. Some other groups argue, however, that providing condoms encourages sexual activity and subverts parental rights and authority. If condom distribution in schools is not allowed, it may be possible to inform students where free condoms are available. Health care providers can play an important role in their communities by advocating for sensible public health policies at local and state levels.

Multiple service settings can be seen as a challenge or as an opportunity. For example, homeless youth constitute a high-risk, underserved group with respect to health. Because their needs cannot be met in traditional medical settings, leaders in cities such as Seattle, Los Angeles, New York, Vancouver, and Toronto have established programs that include free clinics with late evening hours, linkages with community-based youth workers, mobile units providing information and services, telephone hotlines, job training, high school equivalency education, and referral to adolescent-friendly specialists. Similarly, obstetric or gynecologic services are often clustered in a clinic specifically for adolescents, but with adolescent obstetric services provided at different times than adolescent gynecologic services. This model recognizes the differences between pregnant teens and adults (eg, greater need for assistance with high school education, nutrition assistance, child care, and transportation) and the different obstetric and gynecologic needs of teens.

Regardless of the outpatient setting, several considerations need to be given to the needs of adolescents. If space allows, a waiting area with space that is adolescent oriented, apart from space for young children, is optimal. Contemporary posters, magazines, and patient-education materials should consistently focus on adolescents in a positive light. The American Academy of Pediatrics has several health brochures and pamphlets for adolescents ([www.healthychildren.org/english/ages-stages/teen/Pages/default.aspx](http://www.healthychildren.org/english/ages-stages/teen/Pages/default.aspx)). With respect to appointments, arranging clinic schedules at times when teens do not miss school and when only other adolescents are in the waiting room is optimal.

Perhaps the most important aspect of making an outpatient setting attractive to adolescents, however, is the attitude of the clerical and support staff toward adolescents. When adolescents perceive they are welcomed, a positive tone is set for their visit. If teens feel disrespected or disregarded, they may approach a

visit with a negative attitude or fail to keep appointments. In such circumstances, the skills and training of the physician are irrelevant because the staff made the physician inaccessible to the adolescent. Unfortunately, this response may occur for patients who are the most in need of care.

Researchers are developing interactive computer programs that obtain medical history and provide immediate feedback to the adolescent waiting for a scheduled appointment. The information is available to the physician during the visit. Such innovative technology can serve several purposes simultaneously: entertaining, educating, and keeping a medical record.

### Inpatient Settings

Most hospitals, even large, university-based facilities, do not have a separate inpatient unit for adolescents. Despite the advantages of creating an adolescent-oriented therapeutic environment and developing professional staff with expertise to work with adolescents on a dedicated adolescent unit, most institutions do not have the critical mass of specialists with experience (or interest) in adolescent health care nor an average census of adolescent patients to sustain such a unit. Thus, adolescents tend to be admitted to hospital units based on their age (to pediatrics) or their admitting diagnosis (eg, to orthopedics for a fractured femur or to psychiatry for depression). This tendency can result in additional challenges in delivering appropriate inpatient services. For example, in some hospitals the age limit for pediatrics is 16 years, resulting in middle adolescents being admitted to a unit where the average patient age is more than 60.

Hospitalizing adolescents on units based on their admitting diagnosis can present other challenges. For example, orthopedic units may be unprepared to address the psychosocial needs of a 15-year-old boy with attention-deficit/hyperactivity disorder who breaks his femur driving a car while intoxicated and without a license. He would benefit from the unit's staff understanding his need for concrete, concise, and clear explanations of any treatment planned and for consistent and reasonable limits on behavior in the hospital. This model enhances his sense of control over the environment in which he is rendered relatively vulnerable and addresses his need to express his feelings in socially acceptable and productive ways. Otherwise, the hospital unit staff may respond to typical behavior with escalating frustration or punitive restrictions.

Even when adolescents are admitted to a pediatric unit, they may not have their psychosocial needs met if they have chronic symptoms or undiagnosed conditions. If staff members do not understand the mental health needs of these adolescents, especially those with life-threatening conditions or somatic symptoms such as incapacitating headache or abdominal pain, opportunities to help the patient may be missed. For example, the "rule-out" approach, in which an adolescent is admitted for a battery of tests or procedures but is finally judged to have a psychosomatic condition because of a negative workup, is rarely of benefit. The biopsychosocial model recognizes the complex interplay among biological, psychological, and social

factors and includes mental health issues in both the differential diagnosis and the treatment planning for each adolescent patient.

Even if a hospital does not have a geographically distinct adolescent unit, several factors can improve adolescent inpatient services. First, having a recreation room where adolescents can congregate for social interaction and leisure activity, sufficiently far away from patient rooms that noise levels will not bother other patients, is advisable. A child-life professional on staff can ensure that developmentally appropriate activities are available and that the psychosocial needs of hospitalized adolescents (eg, keeping up with schoolwork) are identified. A daily schedule, particularly for anyone in the hospital for more than 3 days, provides structure and predictability and enhances the adolescent's sense of control. Regardless of the length of stay, a unit should have clear rules for adolescents regarding visitors, timing of various activities, temporarily leaving the unit, and schoolwork, among others. Emphasis should be on what the adolescent *may* do, rather than a series of rules on what *not* to do.

In the absence of a geographically distinct unit, cohorting adolescents together is best, rather than distributing them throughout a pediatric inpatient service. A close working relationship with 1 or more physicians who have subspecialty training in adolescent medicine provides important support in staff development and consultation services. Because pediatric residency in the United States includes a mandatory 1-month educational unit in adolescent medicine, most institutions have such a specialist, albeit often as a part-time faculty member. Mental health consultation should be readily available as well. Such consultation may be patient or staff oriented; that is, the mental health services are often requested not only to address diagnosis and treatment for the adolescent, but also to address staff concerns about their response to behavior and how an adolescent's behavior affects other patients and staff on the unit. Similarly, when a simple behavior modification program needs to be established for an adolescent inpatient, the hospital staff may need assistance in its development and implementation.

## HEALTH CARE SYSTEM AND THE DELIVERY OF SERVICES TO ADOLESCENTS

The National Adolescent and Young Adult Health Information Center (NAHIC) has proposed 5 recommendations to improve health for this population as it relates to the individual:

1. Ensure the delivery of high-quality services (by improving training in adolescent and young adult health; by improving workforce distribution to provide health care services; and coordinated support for adolescent and young adult health services)
2. Provide access to comprehensive health services (by ensuring appropriate services are readily available and by implementing strategies to overcome adolescent and young adult barriers to access)
3. Improve financial access to comprehensive health services (by improving existing health coverage and

by expanding coverage for adolescents and young adults beyond existing parameters)

4. Ensure the legal right to health care and confidentiality (by improving legal access to health services and by ensuring legal protection of confidential care)
5. Ensure that services are available, accessible, and appropriate.

In addition, the NAHIC described 5 crosscutting themes related to systems issues (Box 118-3) to improve adolescent health.

## PRACTICAL ISSUES IN PROVIDING ADOLESCENT HEALTH SERVICES

Much of the discussion about challenges to delivering health care to adolescents focuses on adolescents themselves rather than on health care providers. Some specific suggestions have been made in each of the preceding sections of this chapter to enhance services. Additional practical issues, however, deserve consideration (Box 118-4).

This section addresses these issues in the context of a traditional office visit, but the principles apply widely.

Ideally, children enter adolescence having been in the care of a physician who will provide care across

the transition from childhood to adulthood. In anticipation of the emergence of puberty, physicians often advise parents of children around age 8 or 9 about starting to provide the child with some time alone with the physician around the age of 10 years. This policy can be framed in the context of preparing the adolescent to take increasing responsibility for his or her own health (paralleling the increasing responsibility in other domains, such as school and work). At the next visit, the parent can be reminded of the physician's desire to talk to the child alone, usually at the end of the visit.

### Confidentiality

As adolescents progress developmentally, an increasing need for, and right to, confidential care should be honored. This is best addressed at the outset of the visit, and framed in terms of privacy; in most instances it needs to be addressed only once. Two points regarding confidentiality deserve emphasis. First, the ethical principle supporting confidentiality is respect for the person, not keeping secrets from parents. Second, absolute confidentiality should never be offered. A physician might say to the adolescent in the presence of the parent or parents, "It is important for my adolescent patients to have private time with me because by the time they get to be 18 years old, they can see me completely on their own. To help you prepare for that, you will have time at each visit when we talk alone. What we talk about will be between us, unless I think that you or others are in danger—like if you were seriously thinking about hurting yourself. I would only do what I think is in your best interest and I will not go behind your back; but most things we talk about will remain private." Parents are usually comfortable with this policy. If they are not, then there may be a problem with trust in their relationship, which itself might be a focus for intervention.

The electronic medical record (EMR) is a work-in-progress that holds much promise for improving communication, but also presents many challenges with respect to providing confidential health care. Potential threats to privacy include parents accessing information available electronically regarding their adolescent's sexual activity, because this information might be divulged to a physician if the adolescent is aware of possible disclosure to parents. In addition, parents receiving a health insurance "explanation of benefits" (EOB) that includes charges for their daughter's pelvic examination, testing for STIs, and a pregnancy test—all conducted appropriately as part of a confidential and responsible health care visit—could have significant repercussions.

### Private Time With Patients

A question commonly asked by physicians is, "How do I get the parent to leave the room?" A useful technique is to get some background history from the accompanying parent or parents, then give the adolescent an examination gown while saying, "Please put on this gown so that I can do your physical examination. Your mom and dad and I will step out to give you some privacy." Then, after shepherding the parents out of the room, the physician asks if either parent has any

#### BOX 118-3 Improving Adolescent Health Care Systems Issues

- Prioritize the health and well-being of adolescents on a national level
- Coordinate care and reduce fragmentation to maximize existing resources at the local, state, and federal levels
- Use resources effectively, with joint collaborative efforts, and additional sustainable funding to address gaps in adolescent health
- Focus programmatic efforts on primary prevention and early intervention that is substantiated by rigorous research
- Increase the role of families and other meaningful adults who play a critical role in the lives of young people as they transition to adulthood

#### BOX 118-4 Physician Factors Related to Adolescent Health Services Delivery

- Training and experience in providing health care to adolescents and young adults
- Structure and format of the adolescent visit
- Billing and financial considerations
- Referrals
- Transition of youth with chronic illness to adult providers and systems

concerns. This approach gives the parents an opportunity to mention concerns privately. The parents can then be asked to have a seat in the waiting room while the adolescent is examined privately. Again, most parents accept this approach readily. Parents who refuse to leave the room may have trust problems with their adolescent or with the physician; the issue is to avoid having parents feel that they are being “kicked out” of the room. The physical examination is a fairly low-yield procedure in an asymptomatic adolescent, but the adolescent and parents often expect it to be performed. Because adolescents may be sensitive about having a physical examination, it can be less threatening and more efficient to link the history and physical examination. That is, while examining the musculoskeletal system briefly, the physician can ask about physical activity and sports; while listening to the lungs and heart, the physician can ask about issues such as smoking and family history. For example, after listening to the lungs with a stethoscope, the physician can ask “Does anyone you live with smoke?”, leaving the differentiation regarding tobacco or other drugs ambiguous in order to open a discussion about any positive response. As the physician prepares to listen to the heart, he or she can ask “Do you know if anyone in your family has a heart problem?” Depending on the response, the physical examination could be suspended to talk about relevant issues and possibly provide feedback and health education. This approach allows items in the HEADSSS (Home, Education/Employment, Activities, Drugs, Sexuality, Suicide/Depression/Self-image/Safety) psychosocial screening tool to be added at various times in the session in a more conversational manner.

Most physicians allow at least 30 minutes for follow-up adolescent visits, and more for an initial visit. Using structured survey forms, such as *GAPS* or *Bright Futures*, greatly facilitates data gathering, but the information contained in such formats needs to be reviewed before the adolescent leaves the office. The adolescent must know what is going to happen at the visit, how much time has been allotted, and that additional visits may be necessary if all concerns cannot be addressed at once. Electronic screening tools are under development, but most are proprietary.

### Financial Considerations

Billing issues need to be discussed openly and early in the delivery of services to adolescents. Although many adolescents are without health care insurance, in the United States the federal Affordable Care Act promises increased access to care for adolescents and young adults up to 26 years old. Adolescents who are living in poverty or are members of racial or ethnic minority groups are more likely to be uninsured.

Billing appropriately for services is necessary to avoid viewing the adolescent as a source of lost revenue. For patients who do have health insurance, some insurance companies or managed care organizations allow for confidential billing. Alternatively, services can be provided under a broad ICD-10 generic time-based code (such as 99215) when the medical decision-making is of high complexity. For example, a pelvic examination might be recorded in

the chart but not be noted on the bill. The fees for counseling sessions should reflect the time spent. In addition, parents may be willing to pay for bills that do not have a detailed list of services, reassured that their adolescent is acting responsibly toward health maintenance. Adolescents who prefer to pay out of pocket generally need an installment plan but are often more than willing to pay for services with their own money. Finally, patients who cannot pay for services can be referred to free clinics, if they are available locally.

### Specialty Referral

The referral of an adolescent to a subspecialist is most likely to represent a challenge when the subspecialist is a mental health care provider. Adolescents tend to interpret the referral to a psychiatrist, psychologist, social worker, or counselor as an indication that they are “crazy.” To minimize resistance, the physician should let the adolescent know the reason for the referral (“I am concerned that you seem to be feeling very sad, at times hopeless, and recently thinking that life’s not worth living”), to frame the referral in terms of bringing the consultant onto the treatment team (“I want to call on Dr. Smith. He’s a psychiatrist who helps me to help my patients who are feeling the way you are”), and to plan a follow-up so that the referral does not evoke feelings of rejection or abandonment (“I want to schedule a visit in 2 weeks, after you had a chance to talk to him. I want to make sure that things are improving. You also know you can call me if you feel like you’re going to hurt yourself before you see him”).

Patients with chronic conditions, previously fatal during childhood or adolescence, are now living into adulthood. As a result, an increasing awareness exists of the need for the transition from pediatric to adult health care. The transition of care needs to be anticipated and a plan made for this process. This transition of care should occur early in the patient’s life. Hearing from a pediatrician the statement, “and when Jenny gets to be an older adolescent or young adult, we will need to make sure that the physician who will be assuming care for her knows about her cystic fibrosis” is interpreted by parents as positive because it reflects an expectation that she will live to adulthood. Combined training in medicine and pediatrics prepares physicians especially well for the care of such patients, given that no need exists for transfer of care as the patient grows out of the pediatric age group. Physicians with such training are especially well prepared to address the needs of adolescents with complex medical and surgical problems as they progress toward adulthood.

### CONCLUSION

Although caring for adolescents can be challenging, following the principles outlined here enables the physician to provide sensitive, effective care for a group of patients who are often desperately in need of sound health care, thus providing a great service to these patients and a sense of satisfaction for the physician.

## Chapter 119

# INTERVIEWING ADOLESCENTS

Melanie A. Gold, DO, DABMA, MQT; Aimee E. Seningen, MD

The skill of interviewing is tested in the practice of adolescent medicine because the relationship between the adolescent patient and the adult in a position of authority changes rapidly and is often fragile. Good interviewing requires establishing a relationship that enhances communication between the interacting parties. The information most relevant and useful to both people emerges when the relationship promotes communication and respect. Conversely, even skillfully formulated questions do not yield useful information if the interaction between the conversing parties is tense, rushed, hostile, or judgmental.

## WHOM TO INTERVIEW

During adolescence, a transition from dependence to independence should be made by the teenager and facilitated by the parents. In early adolescence, the parents are still largely responsible for their teen’s health care, although by late adolescence, these patients are often managing their own medical needs completely. These changes occur over a relatively brief period; therefore, the physician is faced with assessing the stage of transition toward independence each time the adolescent patient is seen. Whom to interview should be decided in the context of this transition, and the following factors need to be considered.

## ADOLESCENT’S DEVELOPMENTAL LEVEL

Nothing is more upsetting to adolescents than feeling that they are being treated as younger children. This perception is a particular problem in early adolescence, when a teen’s lack of sexual maturation can cause insensitive adults to underestimate the youth’s psychological age. Adolescent patients are often sensitive to the atmosphere of the primary care professional’s office that emphasizes the interests of the young child. Therefore the physician should arrange the office waiting room with a section that contains reading material and decor appropriate for adolescent patients. At least 1 examining room should be equipped and decorated with the adolescent patient in mind. The hospital ward should also have a section furnished and decorated specifically for adolescent patients, and an interviewing room to be used exclusively for teens should be available.

The need for privacy during the interview is never more important than in the practice of adolescent medicine. If the adolescent thinks that the conversation will be interrupted or overheard, then important information may not be revealed. Privacy may be particularly difficult to find on the hospital ward or in the emergency department, but every effort should be made to achieve it.

The interview room should be arranged with the physician, the patient, and the parents seated at the same level, at comfortable conversational distances, and without desks between the professional and the other person or persons to whom the professional is speaking. The few moments needed to rearrange the furniture to meet these requirements are well spent.

### ESTABLISHING RAPPORT

Establishing rapport with an adolescent can be difficult; therefore, the physician should take a genuine interest in the adolescent from the beginning of the interview. Establishing a collaborative partnership with the adolescent patient is important to building trust and setting the stage for developing an effective therapeutic relationship. Greeting the adolescent patient before greeting the parent or guardian is best. Asking the patient to introduce the others in the room can be helpful. The adolescent is then given the message that the primary focus is on the adolescent and that he or she is the expert about the other people in the room. Also helpful is to chat informally with the adolescent patient briefly before the interview begins, being careful to gear the conversation to the appropriate developmental level for that patient. To accomplish this task, the physician should know enough about normal adolescent development to judge the appropriateness of this preinterview conversation. This initial conversation with the adolescent patient can help establish rapport and possibly relieve anxiety the patient may have about the visit.

### PARENTS' ROLE

Although creating an environment in which the adolescent feels comfortable is essential, the physician should not ignore the importance of the parents' role. In early and middle adolescence, the parents' input is critical for a thorough evaluation because adolescents may have limited insight about themselves or inadequate perspective on the timing and importance of symptoms. Adolescents may not be familiar with their own perinatal and birth history, developmental history, previous illnesses, hospitalizations, surgeries, allergies, medications, immunizations, and family history. A portion of the interview conducted with the parent present may help elicit important health history information while giving the adolescent the opportunity to hear and learn about these important aspects of his or her own medical history. Interviewing the patient and parent together initially also gives insight into family dynamics and interaction.

Confidentiality issues should be addressed with both the adolescent patient and the parents before sensitive topics are discussed. The physician should also explain that the adolescent will be interviewed alone for part of the medical history and that the

adolescent may have the physical examination conducted without the parents to ensure confidentiality. Confidentiality and the limits of confidentiality based on state laws or physician comfort should be made clear to the adolescent and the family. The physician should be aware of the particular state's laws regarding the adolescent's rights to confidential evaluation, and these rights must be respected. State-specific guidelines are available from the American Medical Association and the National Center for Adolescent Health and Law. For more information on confidentiality laws by state, see *State Minor Consent Laws: A Summary*, available from the Center for Adolescent Health and Law, or visit their Web site at [www.cahl.org](http://www.cahl.org).

Although adolescents' independence should be encouraged and time should always be set aside for the adolescent to see the physician alone, the appropriate role of the parents should not be ignored. Because of adolescents' possible limited perspective and their need for emotional and financial support, the physician would be wise in most cases to encourage younger adolescents to involve their parents in their medical decision making. When parents are involved, allowing them time to discuss their concerns *without* their child present may also be helpful because they may be reluctant to discuss some concerns in front of their child, such as parental conflict or mental health issues.

### PHYSICIAN NEUTRALITY

If significant disagreements exist between an adolescent and his or her parents, then the physician must avoid the appearance of taking sides on these issues. This task can best be accomplished by interviewing the adolescent and parents together and concentrating on understanding and clarifying their disagreements, thus conveying an appropriately neutral attitude about the conflict. The following vignette illustrates this technique. The evaluation was initiated by the parents, who were concerned that their 15-year-old son had behavioral problems.

Mr. Jones: We think his choice of friends leaves a lot to be desired.

Jim: What's the matter with my friends?

Mr. Jones: Most of them have no ambition. They don't care about school and spend their time just hanging around.

Jim: It's just that we're not like you. You don't care about anything except work. At least my friends know how to have fun.

Physician: Jim, you think your father devotes too much time to work.

Jim: Yeah.

Physician: And, Mr. Jones, you wish Jim were more ambitious and that he would pick friends who are ambitious too.

Mr. Jones: Yes. I worry that Jim isn't going to succeed.

Jim (to his father): I'll succeed in my own way.

Physician: What are your ideas about success, Jim?

In this interaction, the physician has facilitated communication between the father and son by using

reflections and open-ended questions without stating an opinion that would seem to commit to either person's point of view. A review of these issues before the interview helps the physician make a reasonable decision about whom to interview first; no rigid rules apply. The choice depends on the age of the adolescent patient, the person who initiates the contact, and whether conflict exists between the adolescent and parents regarding the problem.

## INTERVIEWING TECHNIQUE

The key to good interviewing is building a trusting relationship among the physician, patient, and parents. This can be accomplished if the physician makes an effort to understand how the adolescent patient perceives the problem and relationships with important people in his or her life. Most health professionals would say that they attempt to understand their patients. However, physicians can often become involved in their own agenda of asking questions and obtaining answers to specific medical questions, and thus miss important clues about their patients' feelings and perspectives. The following vignette illustrates the insensitivity that results when medical issues are pursued vigorously and when the physician becomes more interested in the answers than in establishing a therapeutic relationship. The patient is a 16-year-old girl who has diabetes.

Physician: How much insulin do you take?

Sarah: 16 units of NPH and 4 units of regular each morning.

Physician: Do you test your urine?

Sarah: Yeah.

Physician: How often?

Sarah: Every morning and in the late afternoon, when my mother doesn't bug me.

Physician: Do you ever spill sugar?

Sarah: Sometimes; not too often.

Physician: How much? 1 plus, 2 plus?

Sarah: Just 1 plus a couple of times a week. Mom's always asking me that, but I tell her to leave me alone.

Physician: Do you ever have insulin reactions?

Sarah: Not for a long time.

Physician: How's school?

The casual observer can sense the physician's urgency to "fill in the blanks" of the medical history and that a rushed demanding of information is taking place, illustrated by the series of closed-ended questions asked of the patient without eliciting more elaboration. In the process, this physician has failed to pick up the clues of the mother-daughter conflict. The physician completed the agenda and then turned to a question about the adolescent's life that will probably be perceived by the patient as a mechanical question because the physician did not *hear* the previous comments.

Report can be better established by using techniques to further open communication based on motivational interviewing. These strategies include using open-ended questions, affirmations, reflections, and summaries (the mnemonic is *OARS*). Open-ended questions encourage adolescents to voice their

thoughts or concerns and avoid the feeling of being interrogated by numerous closed-ended questions asked in a row. Affirmations are statements of appreciation of patient strengths or past efforts. Some affirmations show support for patients' sharing information, such as, "I really appreciate that you are able to share that information with me" and "That sounds like a really difficult time for you. I'm impressed that you have taken care of yourself so well." Reflections indicate to adolescents that their perspective is being understood. They can be a simple restatement of what the adolescent has said, or they can be made more complex by extending the meaning of the words or emotions that the adolescent has used. Summaries are often helpful to clarify the problem and pull together the discussion, and they can often help encourage the adolescent to make additional comments.

One strategy to identify salient sources of affirmations is to ask every adolescent to tell the physician about a special attribute by saying "Tell me something about yourself that is special or unique." Explore this fully with open-ended questions and reflections and document this in the chart. The "special attribute" may be as simple as being on the honor roll, excelling at track, helping a parent care for younger siblings, volunteering in the community, or, for an adolescent patient with special health care needs, having academic success in some area. Giving back this information in the form of an affirmation both establishes rapport by helping adolescents feel they are appreciated by the physician and helps adolescents feel good about themselves.

Several problems can arise during the adolescent interview. Adolescents may disclose sensitive issues that they do not feel comfortable sharing with their parents. When this occurs, the physician should help the adolescent identify, when possible, other trusted adults in the adolescent's life (eg, family member, coach, or teacher) who can support the adolescent and be a sounding board for the adolescent to discuss these issues. Rarely, parents may ask for confidential information about their son or daughter, such as whether or not they are using drugs or having sex, or they may request a drug test without their adolescent's knowledge. These issues can be addressed by first having discussions with parents and adolescents about confidentiality early at the first adolescent visit and, when the request for confidential information arises later, to reiterate the limits of confidentiality and when this can and cannot be breached. Often the sharing of confidential information or performing of a drug test can be negotiated with the adolescent who will agree to limited sharing of some information or will agree to a drug test in order to "get the parents off my back" without needing to breach confidentiality and injure the therapeutic relationship between the physician and the adolescent.

Techniques that promote the acquisition of useful information fall into 2 main categories: listening skills and facilitative responses (see interviewing techniques in Chapter 46, Effective Communication Strategies; and Chapter 13, Pediatric History: Assessing the Child). Component aspects of these techniques, discussed briefly in the next 2 sections, are outlined in Box 119-1.

**BOX 119-1 Interview Techniques**

- Listening skills
- Clarification of meaning
- Verbal asides
- Nonverbal communication
- Facilitative responses
- Repetition and review
- Acknowledgment of feelings
- Periods of silence

**Listening Skills**

Unless physicians pay attention to the meaning of words, they often think that they understand the patient's perspective when they really do not. Every time patients use words that are abstract or unclear, physicians should ask for clarification by using open-ended questions or reflections. Skilled interviewers continually ask themselves if they understand what has just been said. In the following vignette, the importance of this technique is illustrated. The patient is a 15-year-old boy who has problems with school.

Nurse Practitioner: Your parents seem concerned about how you are doing in school. What do you think?

Dave: Sometimes I think I'm a wreck.

NP: A wreck?

Dave: Yeah, you know, like I'm a mess.

NP: I don't know, Dave. What does that feel like?

Dave: Like I get these funny feelings, and I think I'm falling apart.

NP: Tell me about one of these funny feelings.

Dave: Well ... sometimes it's like my fingers are growing really big, or small. It's weird.

NP: You mean like parts of your body are changing size?

Dave: Yeah.

NP: What else?

Dave: Sometimes I feel like I'm walking just a little off the ground, like I am floating.

If the nurse practitioner did not pursue the meaning of Dave's words, she might have been left with the vague statement that Dave thinks he is a *wreck*, which many people would assume means that he thinks he is a failure. Instead, the physician now has evidence that Dave is experiencing somatic symptoms of anxiety or psychotic thinking and can pursue the source of these feelings.

Verbal asides are parenthetical statements that often reveal the patient's true feelings but that are stated as though they are unimportant. They usually reflect the adolescent's ambivalence about exposing real feelings. The patient with diabetes described earlier, who said that she tested her urine twice a day "when my mother doesn't bug me," is giving a verbal aside. Statements about her mother constitute unsolicited and important information. Physicians often focus

only on the solicited information and therefore fail to hear such asides. All that is usually required to facilitate further communication is to echo the phrase back to the patient in a simple or complex reflection followed by an open-ended question such as, "It sounds like you are annoyed at your mom. What do you mean when you said she bugs you? Tell me more about that."

Nonverbal communication consists of body movements and facial expressions that reveal a person's feelings. A physician who is preoccupied with asking the right questions, accumulating the answers, and documenting them on the record will miss these important clues. The skilled interviewer learns to divide attention between the words that are being said and the body language of the person being interviewed. Because body language usually is outside the patient's awareness, commenting immediately on such observations may be premature, which may impart discomfort or anxiety on the patient. Part of the art of interviewing is to sense when such comments may be useful. A good rule to remember is that when body language reveals something that the person seems to be trying to hide, it should be left alone. For example, a person's clenched fists may indicate tension when the patient's words suggest calm. However, when a facial expression suggests an inner thought or feeling, then commenting is often useful by using a reflection of emotion. The patient may say something funny, for example, and then seem sad. In this instance, saying something such as, "It looks as if that thought suddenly made you feel sad" is often helpful.

**Facilitative Responses**

The person who is talking usually feels good when the listener can synthesize what the speaker has just said into a summary that reflects the speaker's thoughts accurately. If, for example, the patient has had difficulty finding the right words to describe symptoms and the physician then restates these symptoms briefly and accurately, then the patient realizes that the professional heard what the patient has been experiencing. People like to be understood, and this type of repetition and review using summaries greatly facilitates further communication.

An important component of repetition and review is the acknowledgment of feelings, as well as the recognition of facts and meaning. In many instances, patients make a series of statements that are really meant to build a case for the underlying feelings they are experiencing. If the physician can hear and then acknowledge these feelings with a reflection of emotion or meaning, then the relationship may be significantly enhanced. The following segment of an interview illustrates this interaction. The patient is a 13-year-old girl brought in by her parents because of acting-out behavior.

Physician: Your parents are upset over some of the things you have done. What do you think?

Jen: They really bug me. Last week, Mom wouldn't let me go to the mall with my friends. She said that we were too young to go by ourselves; but all of my friends' parents let them go. Then, a couple of nights

ago, I wanted to stay at Katie's house for dinner, and Dad made me come home. He said that it's getting too dark at night. You'd think I was a baby!

Physician: You don't feel that your parents trust you.

Jen: I know they don't trust me. It makes me feel like doing whatever I want, since they don't trust me anyway.

Physician: It makes you angry that they don't give you more freedom.

Another important facilitative response is the carefully timed use of silences, or pauses. This tactic is particularly important when the patient has difficulty with self-expression. Physicians are usually highly verbal people and respond to such patients by asking more and more questions. When a question has been asked and the response is not immediate, the interviewer should look closely for cues that the patient is processing the question. If the patient seems to be thinking about the answer, then the physician should pause to allow a response. Further statements might include facilitative responses, such as, "What thoughts are you having?" or "It's hard, sometimes, to find the right words." Such replies tend to encourage the response. Similarly, the periods of silence should not be so long that the patient is made to feel uncomfortable. In psychiatric interviews, long silences are sometimes used purposefully; however, this approach would be too threatening for most medical interviews, especially with younger adolescents. Instead, the suggested approach is to allow time for the person whose verbal responses are slow.

## APPROACHING THE SENSITIVE ISSUES OF DRUGS, SEX, AND EMOTIONAL PROBLEMS

Vital issues in adolescent medicine include a healthy response to emerging sexuality and avoidance of addiction to drugs or alcohol. Physicians should address these issues from the perspective of prevention. This approach requires inquiring about these topics throughout the period of adolescent development. However, adolescents and physicians often feel uncomfortable with these issues. Questions about sexual activity, the use of drugs and alcohol, and the possibility of serious emotional problems often seem intrusive and embarrassing. Reassuring the adolescent again about confidentiality is important at this stage of the medical interview. In addition, a useful way to begin the discussion is to explain to the adolescent why these questions are being asked—for example, "I am asking you these questions to help me find out if there is anything that may be putting your health at risk and to tell me what kind of exam and tests I should do."

A tool for assessing the psychosocial history in adolescents is known by the acronym HEEADSSS, used to address issues of home, education or employment, eating, activities in the peer group, drugs, sexuality, suicide or depression, and safety. The HEEADSSS assessment was developed in 1972, refined in 1988, and then updated in 2004. Examples of HEEADSSS questions are summarized in Table 119-1.

Providing an anonymous questionnaire for the adolescent to fill out is another method to help facilitate questioning on more sensitive issues. Such questionnaires usually begin with questions that are medical, such as questions about the adolescent's perception of his or her own weight, skin condition, and development of secondary sexual characteristics. Such questionnaires should include a review of systems with questions about the major organ systems, psychiatric issues, and general complaints such as fatigue and change in appetite. Questions may then move to more sensitive areas such as sexual orientation and activity, use of alcohol and drugs, and exposure to violence and abuse. Questions should also address mental health problems such as feelings of depression, suicidal thoughts, and symptoms of anxiety. The questionnaire should also ask about school performance, including possible problems with teachers or peers. The physician can then use the questionnaire to address issues that are pertinent to the adolescent at the visit. For example, if the adolescent indicates sexual activity is occurring, then the physician can address issues of preventing pregnancy and sexually transmitted infections. If the patient is not sexually active, then the physician can emphasize making informed choices about abstinence and sexual activity in the future. However, a questionnaire should not be a substitute for addressing these issues in person and conducting a thorough history. The questionnaire can be a helpful tool to open up conversation; but questions unanswered or answered as no problem should be addressed during the interview, because problems may be revealed that the adolescent was uncomfortable writing down, especially related to sexuality, substance use, sexual or physical abuse, and mental illness.

When addressing the issue of sexuality with adolescents, care must be taken to avoid making assumptions regarding their sexual orientation. Such assumptions may dissuade adolescents from discussing important medical problems related to their sexual health. The use of gender-neutral terms such as *partner* can keep communication open for discussion of same-gendered attractions. One way of opening a conversation about sexual orientation is to ask, "Many people have sexual experiences with members of the same sex at some point in their lives. Have you had any experiences with other men [women]?" This question can be followed up with questioning regarding whether adolescents consider themselves attracted to men, women, or both, or if they are unsure. The physician should recognize that people who have sex with those of the same gender may not consider themselves to be homosexual. In addition, the physician should be aware that a person's sexual orientation may change throughout the person's life and that adolescents can go through periods of confusion in which they may be unsure or questioning of their sexual orientation. For further information on this subject, refer to Chapter 76, Lesbian, Gay, and Bisexual Youth.

Another helpful approach, especially in addressing issues of drug and alcohol use, is to precede any direct questions about such use with indirect normative statements about the possible use of such substances

Table 119-1	The HEEADSSS Interview
TOPIC	SAMPLE QUESTIONS
Home	<ul style="list-style-type: none"> <li>• Who lives with you at home?</li> <li>• Where do you live? Do you live in a house or apartment? Tell me about your living situation.</li> <li>• Do you share a room or have your own?</li> <li>• Do any new people live in your home?</li> <li>• How are your relationships with parents, siblings, other important relatives?</li> <li>• What are the rules like at home?</li> <li>□ Have you ever been homeless or in shelter care?</li> </ul>
Education	<ul style="list-style-type: none"> <li>□ Have you ever been in foster care or a residential group home?</li> <li>• What school do you go to? What is your grade level?</li> <li>• Are you in gifted, regular, or special education classes?</li> <li>• How do you do in school in terms of grades?</li> <li>• What are your best and worst subjects?</li> <li>• In the last year, how many days of school have you missed? Why?</li> <li>□ Have you ever had to repeat a year of school? Why?</li> <li>□ Have you ever been suspended? Why?</li> <li>▲ What are your educational goals?</li> <li>▲ How connected do you feel to your school? Do you feel as if you belong?</li> <li>▲ Which adults at school do you feel you could talk to about something important?</li> </ul>
Employment	<ul style="list-style-type: none"> <li>• Do you work after school?</li> <li>• What type of work do you do?</li> <li>• How many hours a week do you work?</li> <li>• What are your future career goals? What do you want to do when you grow up in terms of a job?</li> </ul>
Eating	<ul style="list-style-type: none"> <li>□ Do you have any home chores? Do you get an allowance?</li> <li>• How do you feel about your weight? Do you want to weigh more or less or stay the same?</li> <li>• What do you think your ideal or perfect weight should be?</li> <li>• How many meals and snacks do you eat per day?</li> <li>• Tell me what you would eat in a typical day.</li> <li>□ Do you ever skip meals? Why? How often?</li> <li>□ How do you control your weight? With exercise, vomiting, diuretics, laxatives?</li> <li>□ How often do you have a bowel movement? Do you have any problems with your bowel movements?</li> </ul>
Activities	<ul style="list-style-type: none"> <li>▲ What would it be like if you gained (lost) 10 pounds?</li> <li>• How do you like to spend your free time? What do you like to do for fun? What do you particularly excel at?</li> <li>□ What hobbies, clubs, or church or school activities do you have?</li> <li>• What sports do you play, and how many hours a week?</li> <li>□ How many hours of television per week do you watch? How many hours a week are you on the computer (sedentary)?</li> </ul>
Drugs	<ul style="list-style-type: none"> <li>• How much time do you spend with social media such as Facebook and text messaging?</li> <li>• How many of the people with whom you hang out smoke cigarettes, drink alcohol, or use drugs?</li> <li>• How do drinking, smoking, and drugs fit in with your life?</li> <li>• Do you smoke or chew tobacco?</li> <li>• Do you drink alcohol? What kind? Beer, wine, wine coolers, hard liquor?</li> <li>• How often do you use tobacco, alcohol, or drugs? How much and how often?</li> <li>□ Have you ever blacked out or passed out?</li> <li>□ Have you ever done anything you regretted while drunk or high?</li> <li>□ When do you most often use alcohol or drugs? Socially? Alone? Time of day? Day of week?</li> <li>□ How do you feel about cutting back or quitting?</li> <li>• What other drugs have you used or tried? Marijuana, inhalants, cocaine or crack, heroin, pills, LSD, ecstasy, crystal meth, or other drugs?</li> <li>• Do you use anabolic steroids?</li> <li>▲ Have you ever received drug treatment or counseling?</li> <li>▲ How do you support your alcohol or drug use? Have you ever had any arrests?</li> </ul>

**Table 119-1**     **The HEEADSSS Interview—cont'd**

TOPIC	SAMPLE QUESTIONS
Depression and suicidality	<ul style="list-style-type: none"> <li>• How do you usually feel: happy, sad, or a bit of both?</li> <li>• What makes you feel stressed?</li> <li>• What do you do to relieve stress? How do you cope?</li> <li>• Have you ever thought about trying to hurt or kill yourself?</li> <li>□ Have you ever tried to hurt or kill yourself? What did you do? Whom did you tell?</li> <li>□ Have you ever gotten counseling or therapy?</li> </ul>
Sexuality	<ul style="list-style-type: none"> <li>▲ Have you ever been in a psychiatric hospital? Why? How long did you stay?</li> </ul> <p>For female adolescents:</p> <ul style="list-style-type: none"> <li>• How old were you when you started your menstrual periods?</li> <li>• How often do you have a period?</li> <li>• How long are your periods, and how heavy is your flow?</li> <li>• Do you have menstrual cramps?</li> <li>• How often do you miss school because of cramps?</li> </ul> <p>For all adolescents:</p> <ul style="list-style-type: none"> <li>□ When you think of people to whom you are attracted, are they guys, girls, both, neither, or are you not sure? How comfortable are you with your feelings?</li> <li>□ When you think of yourself as a person, do you think of yourself as male, female, neither, or both? How comfortable are you with your feelings of who you are, in terms of gender, on the inside?</li> <li>• Have you ever had the kind of sex in which [add specific type of contact: penis in vagina, mouth on penis, mouth on vagina, penis in rectum, etc]?</li> <li>• How old were you when you first [describe sexual contact]?</li> <li>• How often do you have pain during sexual intercourse or other sexual activities?</li> <li>• How satisfied are you with how often you have sexual relations, and with what you do with your sexual partner?</li> <li>□ Do you have any problems becoming aroused, getting an erection, getting lubricated (wet), or having an orgasm?</li> <li>□ Have you ever been pregnant or gotten someone pregnant? What concerns do you have about being able to get pregnant or get someone else pregnant?</li> <li>□ What have you used in the past to prevent pregnancy? What are you using now? For methods that you stopped, why did you stop them?</li> <li>□ How many people have you had sexual relationships with in your lifetime? What about the last 3 months?</li> <li>□ Have you ever had a sexually transmitted infection such as gonorrhea, <i>Chlamydia</i>, trichomonas, herpes, or warts? What concerns do you have about sexually transmitted infections?</li> <li>□ Have you ever exchanged sex for drugs, money, food, or a place to stay?</li> <li>□ Have you ever sent nude or partially nude pictures of yourself or someone else via cellphone or over the Internet?</li> </ul>
Safety	<ul style="list-style-type: none"> <li>• Have you ever been forced to have sex or been touched in a sexual way against your will? By whom, and is this still going on?</li> <li>• In what ways does that experience affect your day-to-day life?</li> <li>• In what ways does that experience affect your sexual relationships now?</li> <li>• How often do you wear protective sports gear when you play sports?</li> <li>• Have you ever been a victim of violence in your home, neighborhood, or school?</li> <li>• Have you ever been bullied in your neighborhood, school, or anywhere else in your life?</li> <li>• Do you have access to weapons? Is there a gun in your home?</li> <li>□ Do you ever ride in a stolen car, in a car with a drunk driver, in a car late at night?</li> <li>□ Do you use a cell phone or text while you are driving? If so, how often?</li> <li>□ Do you use sunscreen when in the sun?</li> </ul>
Spirituality	<ul style="list-style-type: none"> <li>• What do you consider to be your religion?</li> <li>▲ How often do you participate in religious activities?</li> <li>▲ How important are your spiritual beliefs in your day-to-day life?</li> <li>• How do your beliefs influence your health and attitudes about drug and alcohol use, sex, and contraception?</li> </ul>

• = essential questions   □ = as time permits   ▲ = when situation requires

by others. The following vignette illustrates this approach. The patient is a 15-year-old boy.

Nurse Practitioner: Sometimes kids your age try alcohol, like beer, wine, or mixed drinks, when they're at parties or hanging out together. Have you ever had anything with alcohol?

Justin: Yeah, like, a couple of times.

NP: What was it like?

Justin: Once I was with a friend who was driving and I thought he was, like, kind of crazy. I was really afraid he might get us in an accident.

NP: Was there anything you felt you could do to protect yourself?

Justin: Well, no, but I sure wish there was.

NP: How about yourself? Did you ever feel you drank too much?

Justin: Well, yeah, once I woke up the next day and I couldn't remember anything that happened.

These responses would probably not have been forthcoming had the nurse practitioner asked directly, "Do you drink alcohol or take drugs?" The indirect approach is face saving and is therefore likely to yield more truthful information. The nurse practitioner can now offer more targeted advice. The importance of possible drug or alcohol abuse has also led to screening questionnaires that may be helpful in a population of adolescents at particularly high risk for abuse. Such questionnaires usually assume some alcohol or drug use and are designed to measure the severity of that use and indicate when a referral might be needed. One such method of assessing the severity of drug and alcohol use is the CRAFFT questions outlined in Box 119-2.

## SUMMARY

The interviewing techniques described provide some suggestions for the physician who provides care to adolescents. Effective interviewing requires practice.

### BOX 119-2 CRAFFT Questions

C - Have you ever ridden in a **CAR** driven by someone (including yourself) who was "high" or had been using alcohol or drugs?

R - Do you ever use alcohol or drugs to **RELAX**, feel better about yourself, or fit in?

A - Do you ever use alcohol/drugs while you are by yourself, or **ALONE**?

F - Do you ever **FORGET** things you did while using alcohol or drugs?

F - Do your **FAMILY** or **FRIENDS** ever tell you that you should cut down on your drinking or drug use?

T - Have you gotten into **TROUBLE** while you were using alcohol or drugs?

Two or more YES answers on the CRAFFT suggest a serious problem and need further assessment.

However, the skill is well worth learning because it leads to the completion of better medical and psychosocial histories and improved patient compliance. The result is improved health care for adolescents and their families.

## Chapter 120

# COUNSELING PARENTS OF ADOLESCENTS

Jonathan D. Klein, MD, MPH

Adolescence is characterized by dramatic, often uneven, integration of developmental changes into the daily lives of young people. Teenagers simultaneously experience changing body image, mood swings, burgeoning sexuality, intense need for peer acceptance, increasing independence from family, expectations to achieve, pressure to “act maturely,” and fragile egos. At the conclusion of adolescent development, the emerging young adult is expected to comprehend the nuances of complex issues, arrive at decisions, have developed an ethical and moral value system, prepare for a chosen field of work, and be capable of intimacy. These tasks begin and are realized within family units. Parents often view their pediatrician as a person from whom to seek advice about both physiologic and behavioral issues. The pediatrician’s ongoing relationship with families allows ample opportunity to provide anticipatory guidance and to support parents as their children enter and move through adolescence.

Autonomy and independence evolve over the adolescent years, usually progressing from and within an environment of continuous connectedness to parents and family. This process rarely leads to adolescents achieving independence through a sudden break with their parents; rather, the process is a gradual redefinition of relationships eventually leading to a state of adult interdependence. The adolescent years are one phase of this developmental continuum, as young people continually renegotiate their place within their families. Experimentation and risk-taking behaviors are often perceived negatively, as something to be avoided. Nonetheless, some risks, such as those faced by athletes, performers, or peer leaders, have positive development effects, enhancing self-esteem and leading to competence and mastery. Most adolescents need to experience the tension created by experimenting with ideas and lifestyles that contrast with those of their family. However, during this time of *trying on* diverse personalities, the adolescent also needs to know that return to the safety and refuge of the family is assured.

A parent or guardian’s greatest challenge is to maintain the delicate balance between fostering their adolescent’s independent behavior and supporting the adolescent’s need for trust and security within their family. The tension created by adolescents’ experimentation with ideas and behaviors can be a source of conflict and emotional distress to both parents and young people. Parents may feel a loss of control provoked by the young person’s independent behavior; and adolescents may experience discomfort from feelings of loss of childhood security, as the young person struggles to cope with greater freedom and responsibility. This emotional conflict and pain are often unrecognized and unarticulated; yet these issues underlie many common confrontations between parents and adolescents. Helping parents understand the developmental basis for this conflict may reduce their frustration, as does acknowledging and empathizing with parents about the emotional separation, which may be more painful for them than it is for their adolescent.

## PARENTING GOALS

Pediatricians can help parents navigate their children’s adolescence, beginning with providing parents information about the physical, cognitive, and psychosocial developmental tasks of adolescence and with helping parents realize that adolescent development is a variable process. Parenting styles may be described as authoritarian, authoritative, permissive, or uninvolved. *Authoritarian* parents are demanding and directive, expecting their orders to be obeyed without explanation. *Authoritative* parents are both demanding and responsive, monitoring and communicating standards for children’s conduct and expecting their children to learn self-regulation of behavior. *Permissive* parents do not require or expect mature behavior and generally avoid confrontation. *Uninvolved* parents are neither responsive nor demanding, and they may be neglectful. Although both authoritarian and authoritative parenting styles have been shown to lead to equally good social and vocational outcomes, the former style is often associated with much greater conflict and turmoil for all family members. Parents

should be encouraged to set clear expectations for their adolescents; however, parents should also be encouraged to communicate with their adolescents with 2 major goals. The first goal is to promote communication and resolution of conflict through mutual respect. Parents should maintain the adolescent's trust in the family by speaking respectfully to their child and ensuring that their child speaks respectfully to them. The second goal for parents is to be able to tolerate the adolescent's expression of differing views. When parents can demonstrate this ability and are able to avoid being provoked, the teenager's perception of parental support is heightened, and the adolescent's ego is nurtured. In this way, parents become leaders in a process in which collaboration and mutuality are affirmed, and the ultimate goal of interdependent adult partnership can be achieved.

## PARENT-ADOLESCENT COMMUNICATION

Open communication is probably the most important skill for parents to develop and maintain with their maturing child (Box 120-1). Adolescents need a trusted sounding board, and, as facilitators, parents should listen more than speak. When parents lecture, adolescents shut down. The axiom *actions speak louder than words* makes a more useful parental motto than *do as I say, not as I do*. This latter philosophy seems hypocritical, often diminishing the adolescent's respect for the parent. Such a situation may result in angry confrontations and weakens the parent-teen relationship.

Adolescents' need for parental affection and acceptance, plus their not yet fully developed sense of self, makes them vulnerable to perceived injustices, put-downs, and negative innuendos. Parents gain immeasurably when they respond to their adolescents' feelings with empathetic rather than intellectual responses. For example, during the teen years, peer relationships are characterized by intense emotions consistent with adolescents' egocentricity. Should a break occur in a heretofore close friendship, then the wise parent demonstrates support by empathizing with their child's hurt feelings. Statements such as, "I'm sorry that you are in such pain," "I can imagine how bad you might be feeling," or "It seems that your friend has really hurt you; do you want to talk about it?" express empathy and allow for continued discussion. Sometimes in an attempt to *make it better*, parents tend to minimize the adolescent's pain, perceiving it as "only" a short-lived adolescent

drama. They respond with statements such as, "You'll find other friends," or "Don't worry; you're young and have your whole life ahead of you." Rather than finding this approach helpful, the adolescent may feel misunderstood and may cut off communication, saying, "You just don't understand!"

If the parent did not approve of the friend, then the end of the relationship may be a source of relief for the parent. Telling a teenager to "forget about it" may represent the parent's wish, rather than the teen's. The ultimate negative scenario is a parent who adds, "I told you so!" Thoughtful parents refrain from statements that belittle the adolescent. In fact, adolescents feel devastated when berated by a parent, despite attempts to defend themselves against the hurt by false bravado or an "I don't care!" response. When parents empathize with their teenagers' emotional intensity and allow their youngsters to express emotions without restraint or embarrassment, adolescents are comforted and feel supported. This approach reinforces open communication with parents and minimizes the need for adolescents to act out their angry or hurt feelings.

Parents also have an obligation to clarify expectations, responsibilities, and privileges. However, these decisions are not made in a vacuum, and the parents of adolescents should allow teens to participate as a member of the contractual, decision-making team. The success of a contract between 2 parties requires that each person express *without dissent* what the other person wants. Also important is that both sides *gain something* from the outcome. Win-lose outcomes breed discontent and nonadherence by the person who perceives no gain. These guidelines can be useful when thinking about interactions between parents and adolescents. Open communication and decision making founded on mutual respect are skills that are best learned within a family and ensure a win-win outcome.

The consequences of breaking a contract should be discussed by all involved family members. Few parents have difficulty grounding their adolescent for nonadherence to an agreement, but many have difficulty acknowledging that they, themselves, have failed to abide by an agreement. As an example of this situation, consider a family in which the parents conceded that they nagged their daughter about not spending enough time on school work, fearing her academic failure. The parents agreed with their physician's counsel that they respect the adolescent's privacy and give her responsibility for her school work. A contract was signed by the pediatrician (as mediator), parents, and the adolescent. The terms included the adolescent's decision about the time to set aside for study and the parents' agreement to permit her to experience her decision and to avoid questioning her. If the adolescent's grades declined, then she would be grounded; if the parents continued to nag, then they agreed to be grounded, too.

### BOX 120-1 Dos and Don'ts of Parent-Adolescent Communication

- Listen more, speak less.
- Respond empathetically rather than intellectually.
- Resist saying "I told you so!"
- Clarify expectations.
- Discuss consequences.
- Allow adolescents to participate in decision-making.

## ASSESSING THE PARENT-ADOLESCENT RELATIONSHIP

Pediatricians can assess how families are coping with their adolescents' development by asking parents how parent-teen decision making is handled. Curfews and rules are good issues to discuss with parents because they are a frequent source of conflict, and also

because setting rules and expectations for safe and responsible behavior helps adolescents maintain healthy behaviors and avoid risky behaviors. Curfew decisions include safety issues (which are and should be subject to parental authority) and the issues of adolescent choice of friends and social functions (decisions which are within the adolescent's jurisdiction); thus, they are ideal for discussion of learning about shared decision making and negotiating choices. Physicians should explore whether parents are able to have open discussions with their adolescent about the young person's plans. Do the parents routinely ask about the location of the social function and travel plans? Do they easily agree on curfews with which everyone is reasonably satisfied? In the event of a disagreement, how are compromises negotiated? (See Box 120-2.) Parents should try to avoid arbitrarily rigid limits. An example of the type of statement best avoided is, "I have decided that you are to be home no later than midnight." Such unilateral decisions usually end in angry, unresolvable confrontations. Sometimes the rigidity of the curfew time is confounded by the parents' feelings about the adolescent's choice of friends or activities.

Not infrequently, parental disapproval of an adolescent's friends or activities may be the *expressed* reason for parental inflexibility about the teen's curfew. However, the *underlying* cause for concern may have more to do with the parents' fear that their adolescent might engage in unsafe sexual activity or substance use. The pediatrician might ask the parents whether they and their adolescent have been able to share their views about alcohol and drug use or about sexual activity and relationships and, if so, whether the discussion resulted in mutual understanding. The pediatrician can suggest to both parent and teen that such discussions should take place to make sure that parents have made their values and expectations clear and to encourage communication about responsible behavior and safe decision making.

Parents may also feel anxious because they fear adverse outcomes from their adolescent's behavioral choices. In particular, parents may be afraid that such behavior will become permanent or will threaten the teen's opportunity to mature into a responsible, productive adult. Knowing that extremes of adolescent behavior are generally transient and that most adolescents mature into adults whose lifestyles, values, and mores are similar to those of their families may reassure parents. However, rigid parental control may lead to greater adolescent rebellion. The adolescent's perception of parental acceptance, interest, warmth, and respect is associated positively with the adolescent's self-esteem. Nevertheless, parents should

be supported in their efforts to protect adolescents from injuries and dangerous behavior that may occur during experimental ventures.

Parents should be advised to avoid abdicating their authority. Parental limit-setting is strongly associated with less risky behavior by adolescents. Thus, parents need to be encouraged to maintain confidence in their authority to negotiate limits, particularly when true issues of safety are involved. For example, at a routine visit, in response to a question about how things were going, a mother reported that her 14-year-old son thought he no longer needed a parent. The boy silently rolled his eyes. When each person was given an opportunity to explain, the mother focused on her son's defiant behavior after they denied his request for an extended curfew to join a friend's birthday party at a downtown urban center. The pediatrician encouraged the mother to explain her main objection. She cited her fear for their son's safety, given the lateness of his planned return. At this statement, the boy blurted out: "Why didn't you just say that!" The parents' perceived loss of control undermined their authority; as a result, their son's immaturity became the focus of the confrontation. In this instance, the pediatrician facilitated a reframing of the problem to highlight the safety issues, on which both the parents and the son agreed.

## MANAGEMENT OF PARENT-ADOLESCENT CONFLICT

Some families are intuitively or purposefully flexible and reasonable, and others are able to achieve this with their pediatricians' counsel. However, some families require the intervention of a mental health professional. For example, some parents resist understanding adolescent development and have difficulty acknowledging the mutuality of parent-adolescent interactions. Instead, they chronically respond to the adolescent's point of view with "Yes . . . but," followed by a litany of the adolescent's misdeeds. Other parents are themselves immature and needy and may thus rely inappropriately on the adolescent for nurturing and support. The unmet needs of such adolescents may result in chronic acting-out behaviors, which may include poor school performance, loss of friends, somatic complaints, and, in some situations, depression or suicide attempts. For serious adjustment issues and depressive symptoms, referral to and support by mental health professionals is essential. For less serious adjustment issues, some pediatricians may choose to manage these patients by meeting with the parents to assess their willingness and capacity to understand the developmental and family communication issues and to manage change within the family. (See Chapter 46, Effective Communication Strategies.) If parents are refractory to counseling after 1 or 2 meetings, the pediatrician will be in a better position to make an appropriate mental health referral than he or she would have been at the initial visit. (See Chapter 61, Psychosocial Therapies.)

Pediatricians who counsel parents and adolescents about developing mutually satisfying working relationships can make a significant difference in these families' lives. By enhancing parents' knowledge and increasing their coping abilities, pediatricians can help parents provide a safe harbor for their adolescent

## Chapter 121 ADOLESCENT SEXUALITY

Unab I. Khan, MD, MS; Channele A. Coble, MD;  
Susan M. Coupey, MD

Adolescent sexuality and sexual behavior are best viewed within the context of overall adolescent development. Sexuality is a multidimensional construct and includes ethical, psychological, biologic, functional, and cultural dimensions. The overt expression of sexuality

depends on the biopsychosocial environment in which the individual exists. Biologic changes at puberty prime the adolescent brain and body for reproduction, and individual and family psychodynamics influence sexual behavior. The larger sociocultural environment sets the norms for sexual behaviors and controls them through its institutions, including religious organizations, schools, government, and the media. As adolescents experiment with sexual expression, they inevitably make errors of judgment. Most such errors are minor, but many have significant health consequences.

Pediatricians and other physicians are in an ideal position to provide longitudinal sexual health care to children and adolescents as part of preventive care and to help adolescent patients maintain their sexual health (Box 121-1). Traditionally, monitoring pubertal changes and providing anticipatory guidance to adolescents and their parents regarding timing of the growth spurt or onset of menstruation have been viewed as appropriate tasks for pediatricians. However, with initiation of sexual intercourse at younger ages, pediatricians caring for teens should also be able to provide preventive care related to sexual behavior, including contraceptive counseling and prescription, screening for sexually transmitted infections (STIs), and counseling related to issues of sexual orientation and abuse. In addition, because of a high prevalence of health problems stemming from sexual behavior in the adolescent age group, pediatricians must be able to diagnose and manage conditions such as pregnancy, STIs, sexual dysfunction, and sexual victimization. As part of health maintenance, physicians can play an active role in a young adolescent's perception of healthy sexuality. The physician's role is not limited to providing direct care—schools and other community organizations can often benefit from

### BOX 121-1 Adolescent Sexuality: Role of the Pediatrician

#### ANTICIPATORY GUIDANCE

- Pubertal development
- Postponing coitus
- Safer sex practices

#### DIAGNOSIS, TREATMENT, AND REFERRAL

- STIs
- Pregnancy
- Sexual dysfunction
- Sexual victimization

the expertise of team members, who may help design sexuality education classes, pregnancy prevention programs, or HIV and AIDS prevention initiatives. This expanded societal role gives pediatricians a broader influence on adolescent sexuality than is possible within the patient-physician-family relationship.

## PUBERTAL DEVELOPMENT AND SEXUALITY

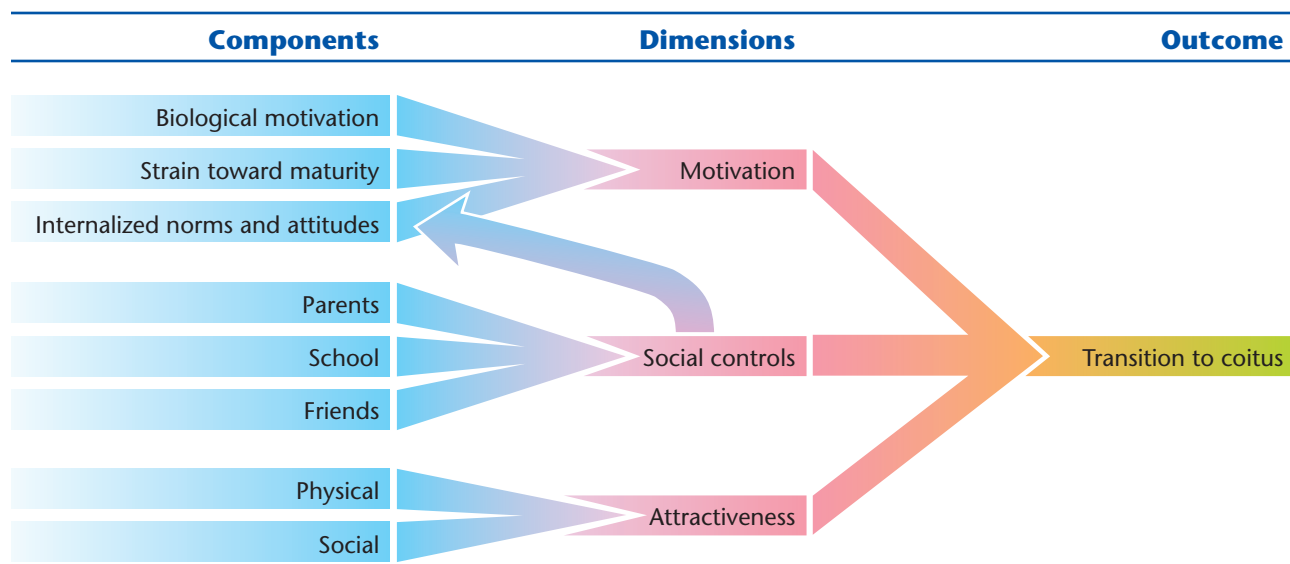

In the United States, most girls enter puberty at age 9 or 10 years, reach menarche on average at 12½ years, and achieve full fertility by age 15 or 16 years. On average, black girls reach each stage of puberty 9 months earlier than white girls. Boys begin pubertal development somewhat later than girls, at age 11 or 12 years, produce sperm (spermarche) and have their first ejaculation on average at age 13 or 14, and achieve full fertility at approximately age 16 years. Thus, by middle adolescence, most boys and girls have completed the biologic developmental requirements for reproduction.

Puberty is accompanied by a surge of hormones in both sexes. Androgenic hormones are primarily responsible for sexual motivation (libido) and pubic and axillary hair growth in both boys and girls and for the increase in muscle mass and skeletal growth in boys. Estrogenic hormones are important for skeletal growth in both sexes and for breast and uterine development and body fat redistribution in girls. (See Chapter 185, Puberty: Normal and Abnormal.) Sex hormones have a direct effect on the brain, and as their levels increase during puberty the adolescent's sexual interest is stimulated. Most adolescents report their first experience of sexual attraction occurred between ages 10 and 12, with the first sexual fantasy occurring several months to a year later. Changes in the adolescent's outward appearance signals to others in

the environment the individual's readiness for sexual intercourse (Figure 121-1). Hence girls who are early developers are at risk for early initiation of intercourse.

Social factors can either facilitate or inhibit sexual expression. Researchers who propose a biopsychosocial model have identified individual attributes correlated with adolescent sexual behavior, such as testosterone levels, physical maturation, and temperament and personality, as well as social influences such as religiosity and friends' behaviors. Differences by race and ethnicity are found for some adolescent sexual behaviors. Black and Hispanic adolescents are more likely to report early initiation of sexual intercourse than are white adolescents, and boys report sexual intercourse at an earlier age than girls. Postponing sexual initiation in girls is also associated with later pubertal development (menarche at age 13 years or later), higher parental education, 2-parent families, careful parental supervision, good communication with mother, and high educational aspirations. Sociocultural influences are less well understood for male coital behavior, and few studies have looked at factors that are associated with postponing sexual initiation in boys.

Intervention trials have shown the importance of sexual education in middle schools to prevent early initiation of sexual intercourse. A program developed by Howard and McCabe entitled *Postponing Sexual Involvement: Educational Series for Young Teens* was used with all eighth grade students in 24 Atlanta city schools and was evaluated in the mid-1980s. The evaluation found that the program was helpful to both boys and girls. By the end of the ninth grade, boys who had not had sexual intercourse before they participated in the program were significantly more likely to postpone sexual involvement than were similar boys who had not participated. The results indicate that boys do respond to educational intervention aimed at helping them control their sexual behavior. However, in this

**Figure 121-1** Conceptual model of transition to coitus in adolescence. (Modified from Udry JR. *Hormonal and social determinants of adolescent sexual initiation*. In: Bancroft J, Reisch JM, eds. *Adolescence and Puberty*. The Kinsey Institute Series. Vol. 3. New York, NY: Oxford University Press; 1990. Reproduced with permission from The Kinsey Institute for Research in Sex, Gender, and Reproduction.)

study 44% of the eighth grade boys (ages 13 and 14 years) had already initiated sexual intercourse before the program was given, and these sexually experienced boys did not benefit from the intervention. Tortolero and colleagues conducted a randomized controlled trial using a sexual education program focusing on HIV, STI, and pregnancy prevention that was taught at 5 of 10 urban middle schools in Texas, while the other 5 schools received standard health education that varied by school. The authors found that compared with schools with standard health education, the schools with the sexual education program had an overall lower prevalence of sexual initiation by ninth grade (23% vs 30%). However, girls in the schools with the sexual education program showed a significantly lower risk for initiating sexual activity (adjusted risk ratio = 1.42), whereas boys' risk for sexual initiation was not different between the intervention and control schools.

## ADOLESCENT SEXUAL BEHAVIOR

### Definitions

*Gender identity* refers to an individual's innate sense of being male or female and develops in early childhood. *Gender role* is influenced by societal and cultural norms and refers to the outward expression of the individual's sense of maleness or femaleness to the outside world. *Sexual orientation* refers to an individual's pattern of physical and emotional arousal toward others. *Sexual behavior* refers to the actual sexual acts in which an individual engages. During adolescence, sexual orientation and sexual behavior are not necessarily congruent.

### Prevalence of Sexual Intercourse

In most developed countries most youth become sexually active during their teenage years. At least 70% of

adolescents have had intercourse by the age of 19 years. Even though the mean age at which adolescents become sexually active does not vary significantly among European countries and the United States, European adolescents are less likely to have sex before age 15 years, more likely to use contraceptives, and have substantially lower pregnancy rates. However, US adolescents are waiting longer to have sex now than they did in the recent past. In 1995, 19% of girls and 21% of boys became sexually active before the age of 15 years. However, by 2006–2008 only 11% of girls and 14% of boys reported becoming sexually active before age 15 years. In addition, the use of contraceptives at first sexual intercourse has increased from 76% in 2000–2004 to 84% in 2005–2008.

Large changes in adolescent sexual behavior have occurred since the 1960s and continue to evolve. Several high-quality longitudinal data sets link sexual behavior to demographic characteristics in adolescents in the United States. These data include the National Survey of Family Growth for Females, the National Survey of Adolescent Males, the Youth Risk Behavior Survey (YRBS), and the National Longitudinal Survey of Adolescent Health (Add Health). Although findings vary somewhat among individual studies, the trends are consistent. From 1991 to 2001, as measured by the YRBS, the proportion of male and female high school students in the United States reporting any sexual intercourse fell from 54% to 46%, with the greatest drop seen among white adolescent males. From 2001 to 2013, the proportion of students reporting sexual intercourse has been unchanged at 47%. Data from the 2013 YRBS survey of US high school students are summarized in Table 121-1.

Sexual behaviors among adolescents who have made the transition to sexual intercourse have also

**Table 121-1 Sexual Behaviors Among High School Students in the United States, 2013**

INFORMATION SURVEYED	ALL (%)	BOYS (%)	GIRLS (%)
<b>EVER SEXUALLY ACTIVE</b>			
Students who have ever had sexual intercourse	46.8	47.5	46
<b>RACE-ETHNICITY</b>			
White	43.7	42.2	45.3

<b>HEALTHY BEHAVIORS</b>			
Currently active students who used a condom at last intercourse	59.1	65.8	53.1
Students who were ever tested for HIV	12.9	11.2	14.6

Data from Kann L, Kinchen S, Shanklin SL, et al. Youth risk behavior surveillance—United States, 2013. *MMWR Surveill Summ*. 2014;63(Suppl 4):1–168.

been studied. Of adolescents who are sexually active, most practice serial monogamy; that is, they have only 1 sexual partner at a time. Nevertheless, boys and girls who begin having intercourse in early or middle adolescence will often accumulate 3 to 5 different sexual partners before they leave their teens. We do not know what percentage of young people have intercourse once or twice and then stop the behavior for months or years. Some studies indicate that younger adolescents who are unlikely to be living with a sexual partner have intercourse infrequently. For example, sexually active, 15-year-old boys report an average of nearly 8 months of the year without a sexual partner.

### Noncoital Sexual Behaviors

Recent studies indicate that noncoital sexual behaviors are practiced with increasing frequency among adolescents. In 2008, Add Health found that by the age of 18 years, more than two-thirds of US adolescents have engaged in vaginal or oral-genital sexual activity, but only about half reported both, and about 1 in 10 adolescents reported anal intercourse. In addition, one-third of the adolescents who initiated sexual intercourse initiated oral-genital and vaginal intercourse within a 1-year period, suggesting that oral-genital intercourse did not postpone initiation of vaginal intercourse for most adolescents.

In a longitudinal survey conducted in 2005 of almost 600 ninth graders in California, 20% reported having had oral sex compared with 14% reporting vaginal sex; and 32% of students intended to have oral sex in the next 6 months, whereas 26% planned to have vaginal sex. In addition, these ninth graders perceived oral sex as having significantly less risk than vaginal sex on health, social, and emotional consequences. However, oral sex has also been associated with high-risk behaviors. Prinstein and colleagues reported that adolescents who were engaged in oral sex alone had more sexual encounters, had more partners, and were less likely to use condoms compared with adolescents engaging in vaginal intercourse alone.

### Masturbation

Masturbation is a common sexual behavior in adolescents. Smith and colleagues surveyed 15- to 18-year-old Australian adolescents and found that 59% of boys and 43% of girls reported having masturbated. In a 2009 study conducted in the United States, Robbins and associates reported masturbation rates as high as 74% in males and 48% in females, and other studies show rates as high as 90% to 94% in males and 50% to 60% in females. Despite high prevalence of the behavior, masturbation is still given little attention in research, clinical settings, and sexuality education curricula.

### Homosexual Behavior

Historically, homosexual behavior was often overlooked in studies of adolescent sexuality, but current research more often documents trends in homosexual and bisexual behaviors among adolescents. Only in the past few decades have any studies of large representative populations tackled the issue of sexual orientation in adolescence. (See Chapter 76, Lesbian,

Gay, and Bisexual Youth.) Data from the 2008 National Survey of Family Growth indicated that 3% of males and 8% of females aged 18 to 19 years identify themselves as homosexual or bisexual. The 2001–2002 Add Health study found that 5% to 13% of students in grades 7 through 12 reported some degree of same-sex romantic attraction and 1% to 3% reported same-sex behaviors. In addition, of the students identifying themselves as “mostly heterosexual,” almost 6% of males and 15% females reported bisexual behavior. The 2013 YRBS found similar rates of US high school students identifying themselves as gay or lesbian (1% to 3%) and bisexual (3% to 5%).

In the past, girls were thought to develop a homosexual identity at an older age than boys, often not until young adulthood or later. In a study of 100 bisexual and lesbian young women (ages 16–23 years), who were followed for 10 years, Diamond and colleagues found that homosexual female behaviors varied over time in a nonlinear fashion; some of the young women experienced what the authors termed “an abrupt emergence of novel erotic feelings and experiences,” whereas others reported “periodic episodes of reorganization in sexual identity.” The authors found that women were more likely to report bisexual attractions than to report exclusive same-sex attractions; to show a greater capacity for change in same-sex attraction over time and across situations; and to ascribe a role for choice and circumstance in their same-sex sexuality.

### Adolescent Sexuality and the Media

Adolescents seek and receive a great deal of information about sexual behavior and sexuality from media, whether actively going to Web sites for answers to questions or passively watching sexualized programs on TV. In the United States, 95% of adolescents regularly “go online,” and 71% use more than one social networking site (SNS). The Media Practice Model suggests that the “media diet” chosen by adolescents is a reflection not only of who they think they are but also who they want to be. Studies show that social media use may have a significant effect on the social and sexual well-being of adolescents. Multiple studies found a significant relationship between viewing sex in the media and adolescent sexual behavior (including early sexual debut) as well as influence on youths’ attitudes and beliefs about sex and sexuality. Online disinhibition may lead to divulging private information more readily than in a face-to-face interaction. In addition, daring and high-risk behaviors may lead to more “likes” by the audience, thus perpetuating such behavior. In a cross-sectional study, 54% of SNS profiles were found to contain 1 or more references to a high-risk behavior such as sexual activity, substance abuse, or violence. Self-exploitative behaviors such as creation and distribution of explicit or inappropriate materials, photos, comments, and suggestions may also occur on Internet sites.

Other adolescents may participate in “sexting,” which refers to the sending, receiving, or forwarding of sexually explicit messages, photographs, images, or videos through the Internet, by cell phone,

or another digital device. In a longitudinal study, Temple and colleagues reported that 28% of their subjects had received a “sext” and 57% had been asked to send a sext. In addition, sexting increased the likelihood of high-risk sexual behaviors in female adolescents.

Despite these real concerns, digital media have afforded opportunities for the breakdown of geographic boundaries in health promotion, especially sexuality education. Web-based interventions can be tailored to the cognitive developmental stage of the target audience and can reach underserved youth more easily, especially when it comes to dissemination of sensitive information that adolescents may not feel comfortable discussing in face-to-face interactions. In a review summarizing the effectiveness of digital media-based sexual health interventions in adolescents, Guse and colleagues reported a positive attitude of adolescents toward Web-based interventions. From studies utilizing SNSs to prevent the decline of condom use among adolescents to investigators using SNSs to provide accurate and age-appropriate STI information, educators are working to take advantage of SNS popularity in adolescents. Thus, despite the potential negative consequences of digital media, SNSs can serve as valuable tools for adolescent care providers and educators. Continuing challenges include providing accurate, relevant information and ensuring confidentiality for youth.

## HEALTH CONSEQUENCES OF ADOLESCENT SEXUAL BEHAVIOR

### Sexually Transmitted Infections

Adolescents represent one-fourth of the sexually active population but account for nearly half (9.1 million) of the 18.9 million new cases of STIs each year. Young people who begin to have sexual intercourse in early or middle adolescence are more likely to develop an STI than those who postpone intercourse until later adolescence or adulthood. This is due both to anatomic and behavioral factors. Cervical ectopy, a normal feature of the anatomy of the cervix in adolescent girls, increases the risk for acquisition of STIs. For young adolescents, romantic relationships may last only a few days or weeks, and younger sexually active teens may accumulate several different sexual partners by the time they reach adulthood. Thus they are more likely to be exposed to STIs than are their peers who wait until they are older to initiate sexual intercourse and whose relationships usually last months or years. In addition, asymptomatic STIs are prevalent in both boys and girls and contribute to the spread of infections. Because of the many barriers adolescents face in obtaining routine STI screening and gynecologic care, asymptomatic infections are likely to go undetected and untreated unless or until they become symptomatic. Newer nucleic acid amplification tests that can be performed on urine specimens and do not require genital examination should help with the detection and control of asymptomatic infections.

Some STIs are associated with a high rate of permanent damage to the reproductive tract, especially for

girls. For example, salpingitis or pelvic inflammatory disease caused by *Chlamydia trachomatis* is the leading cause of acquired infertility in women. Chlamydia infection remains the most common reportable STI in the United States. The Centers for Disease Control and Prevention national surveillance data show an increase in chlamydia rates since the late 1980s, thought largely to be because of enhanced screening efforts and the availability of more sensitive testing modalities. Adolescent girls aged 15 to 19 years have the highest age-specific rate of infection, with more than 3,000 cases per 100,000. There are also racial disparities in chlamydia infection rates, with black adolescents having 6 times higher rates than white adolescents. Similar disparities exist with gonorrhea rates. For example, black adolescent males have a rate of gonorrhea that is 36 times higher than white male adolescents.

Human papillomavirus (HPV), the most common STI in adolescents, can cause cancer of the cervix, vulva, anus, penis, and oral cavity as well as genital warts; studies of adolescents report that up to one-third of sexually active girls are infected with this virus, although most are completely asymptomatic. In 2006, the American Academy of Pediatrics recommended routine vaccination with the quadrivalent HPV vaccine for all adolescent girls. In 2011, the recommendation was revised to include both male and female adolescents aged 11 to 26 years. Despite these recommendations, rates of vaccination in the United States continue to be low. In a sample of US adolescent females (ages 14-17 years) 50% of those surveyed initiated HPV vaccination and only 38% completed the vaccine series. Common factors associated with non-vaccination included parental concerns with vaccine safety and health care providers not recommending the vaccine. Data from Australia, where the vaccination rate of adolescent girls has been very high for several years, already show a reduced rate of HPV infection, and there is every expectation that with longer follow-up, a reduced rate of HPV-related cancers will be documented.

Human immunodeficiency virus infection continues to occur among adolescents, especially those in certain subgroups of the population. Factors found to be significantly associated with HIV seropositivity in adolescents include early age at sexual initiation, having older sex partners, having been sexually abused, engaging in survival sex, having sex under the influence of drugs or alcohol, using multiple drugs, having sex with casual partners, having had an STI, and engaging in male homosexual relationships.

### Unintended Pregnancy

Unintended pregnancy is one of the most socially significant issues related to adolescent sexual activity. Adolescent mothers are more likely to drop out of school, face unemployment, live in poverty, and rely on public assistance than are their peers who do not have children. The children of adolescent mothers have more health and social problems than children of adult women as well. In the United States, from 2000 to 2008, among women younger than 20 years of age, pregnancy rates declined by 19% and birth rates declined by 16%.

The Alan Guttmacher Institute reported that in 2008, for every 1,000 women aged 15 to 19 years, there were 68 pregnancies, 40 births, and 18 abortions. Part of the reduction in teen pregnancy rates in the United States can be explained by increased condom use. As shown in Table 121-1, almost 60% of sexually active high school students in 2013 used a condom at last intercourse, and this is a significant increase from the 46% using condoms in 1991. Despite the significant decline in US teen pregnancy rates from the 1990s to 2000s, the rate in the United States is still very high (68 per 1,000) compared with other developed countries such as Canada (28 per 1,000) and Sweden (31 per 1,000). The primary reasons for the high teenage pregnancy rate in the United States include less overall contraceptive use and less use of the most effective contraceptives, that is, hormonal methods. Other reasons include negative societal attitudes toward teenage sex, restricted access to reproductive health services, and ambivalence toward contraception.

### Depression and Suicide

Depression is quite common in the adolescent population, as are suicide ideation and attempts, and sexuality issues are often linked to these mental health problems. In community samples, the 6-month prevalence of depressive disorders in adolescents is 5% to 6%, with the lifetime prevalence reaching 15% to 20%. Depression is the leading risk factor for youth suicide. According to the 2011 YRBS, nationwide almost 16% of high school students had seriously considered suicide in the previous year, and 8% had made an attempt. Forced sexual activity is a risk factor for suicide, and 7% of students surveyed in the 2013 YRBS reported being physically forced to have sex (Table 121-1). In both genders, having sex before age 13, injection drug use, and being forced to have sex are associated with suicidality. Adolescents who identify themselves as gay, lesbian, or bisexual are also at high risk for suicide. In a sample of more than 2,000 high school students in San Francisco, the students who identified themselves as homosexual or bisexual had a 3.6 times greater risk for suicide attempts in the past year compared with their heterosexual peers.

### Sexual Victimization

Sexual abuse should always be considered a possibility when an adolescent has very early onset of sexual activity. Both adolescent boys and girls who have been victims of forced sex, either as young children by an adult perpetrator or as adolescents, have higher rates of health risk behaviors and mental health problems. Prevalence rates of child and adolescent sexual abuse vary in the literature depending on the definition of abuse. A telephone survey conducted in 1995 of a national household probability sample of more than 4,000 adolescents aged 12 to 17 years using a very clear and explicit definition of sexual abuse found 8% of adolescents reported being victims of sexual abuse. The survey found that a prior history of sexual abuse correlated significantly with young age at onset of voluntary sexual intercourse, unintended pregnancy, suicide attempts, drug and alcohol abuse, eating

disorders, and violence. Girls who have been sexually abused are twice as likely as those not abused to have had intercourse by age 15 years and 3 times more likely to have been pregnant. Thus it is important to explore the possibility of sexual abuse when an adolescent has very early onset of sexual intercourse or has multiple behavioral problems.

An often-overlooked subset of adolescent victims of sexual abuse are those involved in sex trafficking. Sex trafficking is defined as the recruitment, harboring, transportation, provision, or obtaining of a person for the purpose of a commercial sex act. Seventy percent of women involved in prostitution were introduced into the commercial sex industry before age 18 years. The average age at which children are being lured into commercial sex exploitation is between 11 and 14 years. The first US national level data on human trafficking became available in 2008. The US Department of Justice found that from 2008 to 2010, 40% of more than 2,500 cases of human trafficking in the United States involved minors. Adolescents from any socioeconomic background and any ethnic or racial group can become a victim of sex trafficking. However, poverty, isolation, drug addiction, violence in the family, school failures, a history of childhood sexual abuse, family dysfunction, or criminal behavior make adolescents both emotionally and economically vulnerable.

### Sexual Dysfunction

Sexual dysfunction is an area not well studied in adolescence, although the prevalence in both boys and girls is probably quite high. Clinical reports indicate that many sexually active adolescent girls do not enjoy sexual intercourse and have never reached orgasm. Reasons for engaging in the behavior have more to do with intimacy and closeness to the partner than with personal sexual gratification. Occasionally a girl who is anxious and unsure about sexual activity or who has previously been abused develops vaginismus. Large numbers of adolescent boys are thought to have premature ejaculation, but they rarely complain of the problem. Erectile dysfunction does occur in adolescence, often as a result of “performance anxiety” and other psychogenic causes. Heavy alcohol or marijuana use can be responsible for erectile dysfunction and should be explored in the medical history. Prescription medications (eg, antihypertensives, antipsychotics, and antidepressants) often are implicated in erectile dysfunction in men and anorgasmia in women. Other drugs that cause sexual dysfunction and that may be taken by adolescents are cimetidine, ranitidine, sulfasalazine, and some anticonvulsants.

## ADOLESCENT SEXUALITY AND THE PATIENT-PHYSICIAN-PARENT RELATIONSHIP

Even though sexual feelings and behaviors are of great concern to adolescents and their families and adverse effects of sexual behavior are common in this age group, most patients and parents will avoid introducing the subject at the health care visit. Pediatricians can set the stage for frank, honest discussions of

feelings and behaviors that often are embarrassing, shameful, and psychologically painful.

All physicians should pay particular attention to privacy for both adolescent patients and parents. In general, the medical interview with the adolescent should take place in private. Studies show that giving assurance of confidentiality increases the number of adolescents willing to return for future visits. Every physician should be aware of the individual state laws that exist regarding diagnosis and management of STIs, contraception, and termination of pregnancy. To give optimal care to adolescents, physicians should be open, honest, interested, concerned, and supportive and should tailor their communication style to the developmental and functional level of the adolescent. Asking questions that do not make assumptions or presuppose certain behaviors is important, given that adolescents are more likely to disclose closely guarded information when interviewed in this way. For example, if the pediatrician assumes that everyone is heterosexual and asks girls if they have a boyfriend and boys if they have a girlfriend, adolescents who are questioning their sexual orientation or who know they are homosexual will be unlikely to offer this information. If, on the other hand, the question pertains to sexual attraction to women, men, or both men and women or includes a gender-neutral term, such as sexual partner, then the adolescent is more likely to share information. Similarly, asking open-ended questions in the context of peer behavior is more likely to yield important information. Questions can begin with “Most adolescents at this age are interested in exploring . . .” or “Are you aware of anyone in your class who is involved in . . .”.

Some adolescents who have been abused are afraid to disclose painful secrets because they have not yet developed a secure, trusting relationship with the physician. The physician should understand this factor, should avoid pushing too hard and too soon for disclosure, and should explore the topic in more depth at a later visit when the relationship has had a chance to develop.

Negotiating confidentiality between adolescents and parents around sexual issues is a delicate area for the patient-physician-parent relationship. When a problem is diagnosed the specifics of what will be disclosed to parents need to be discussed in advance with the patient. For the physician to lie to parents would be unprofessional and set a bad example. However, disclosing all of the details of the situation is usually unnecessary. For example, a 16-year-old girl being seen for her annual health supervision visit reveals that she has recently become sexually active. She reports that she has had 2 partners in the last 8 months. She complains of a slight vaginal discharge. The physician discovers mucopurulent cervicitis during a pelvic examination and prescribes appropriate antibiotics. What should the mother be told? Most adolescents would agree to allow the physician to tell the mother that a pelvic examination was performed and an infection was noted that is easily treated with antibiotics. The physician can tell the adolescent beforehand that if the mother asks directly whether the infection is sexually transmitted, she will be told

that information about her daughter's sexuality is kept in confidence. However, the adolescent patient should know that the physician will encourage a dialogue between mother and daughter about sexual behavior. The physician must resist acting as a go-between in the mother-daughter relationship and should emphasize the necessity of direct communication between parent and child. At the same time, it is important to help parents communicate clearly to their adolescents about sexual issues because this may have the added benefit of making teenagers less likely to rely on peers for advice and less likely to conform to peer norms. It is the physician's role to help parents develop the skills to communicate effectively with their teenage children. Studies have shown that parent-child connectedness and clear communication about sexual issues have been associated with delay of sexual initiation.

An integral part of caring for adolescents is providing developmentally and functionally appropriate anticipatory guidance. An important point to remember is that the early adolescent still retains concrete thinking. Given the increased awareness of physical changes, these factors need to be addressed and explored during this stage. If the adolescent is not sexually active, then the adolescent should be encouraged to postpone coitus to a later stage. In middle adolescence an increase in risk-taking behaviors often occurs. Counseling at this stage should focus on safer sex practices and contraception as well as on postponing intercourse. Anticipatory guidance should also include a discussion of signs and symptoms of STIs and the need for regular screening. By late adolescence, patients should be encouraged and empowered to negotiate the health care system and make decisions regarding their reproductive health. Pregnant adolescents should be offered options counseling in a safe, nonjudgmental, and trusted environment.

## SUMMARY

Providing health care related to adolescent sexuality is one of the more difficult tasks of the primary care physician. It requires in-depth knowledge of pubertal and psychosexual development, familiarity with the norms of adolescent sexual behavior, knowledge of pertinent gynecologic and urologic medicine, and superior communication skills. Adolescents are in great need of this type of care and are very appreciative when it is done well; most adolescents want to be sexually healthy and eventually to have children and raise healthy families themselves.

## Chapter 122

# ADOLESCENT PREGNANCY AND PARENTHOOD

Dianne S. Elfenbein, MD; Marianne E. Felice, MD

Teenage pregnancy and parenthood are a national concern. They frequently result in societal, economic, and educational disadvantages for teen mothers and their babies. Likelihood of teen pregnancy is influenced by many factors: individual goals, societal pressure, family values, pubertal timing, age at first intercourse, risk-taking behaviors, and knowledge of contraceptive choices, among others. Although the United States has higher rates of births to teen mothers than most other industrialized nations, these figures have decreased since the late 1950s (Figure 122-1). Declines in teen birth rates have been accompanied by decreases in rates of pregnancy, induced abortion, and fetal loss.

**Figure 122-1** Birth rates for teenagers aged 15 to 19 years, by age group: United States, 1960–2013. (From Martin JA, Hamilton BE, Osterman MJK, et al. *Births: final data for 2013*. Natl Vital Stat Rep. 2015;64(1).)

From 1991 to 2013, decreases occurred in the teen birth rates of all racial and ethnic groups, with the greatest decrease for non-Hispanic black teens (67%) and Asian/Pacific Islanders (68%). Birth rates for non-Hispanic white teens dropped 57%, and rates among Hispanic teens dropped 60%. The future will tell if this trend continues.

The decrease in the rates of adolescent pregnancies and births seems to be the result of several factors, including delayed initiation of sexual activity, increased use of contraception (eg, condoms) at first coitus, and a greater efficacy of contraceptive methods. All hormonal methods remove the act of pregnancy prevention from the act of sexual intercourse and are more effective than barrier methods, spermicides, or methods based on the periodicity of the menstrual cycle. Methods such as injectable or implantable contraception and newer hormonal delivery systems such as patches and intravaginal rings do not require the need to take a pill every day, which may be difficult for young women who may not have regular life routines. Implants and intrauterine devices have been recommended as preferred contraception for teens by the American Academy of Pediatrics and the American College of Obstetrics and Gynecology.

### CHARACTERISTICS OF TEEN PARENTS

Teens growing up in conditions of poverty are known to be at the highest risk for early pregnancy. In addition, pregnancy rates differ for young women of different racial and ethnic groups; marked changes in the rates of each group have occurred over the past 40 years. Data from 2013 indicate that Hispanic teens aged 15 to 19 years have the highest birth rates of their age group (41.7 live births per 1,000), in contrast

to non-Hispanic black teens (39.0) and non-Hispanic white teens (18.6) or Asian/Pacific Islanders (8.7). More than two-thirds of all births in the age range of 15 to 19 years were to 18- to 19-year-old women. Numerically, births to women younger than 15 years represent a small proportion of overall births; however, in this age group, black mothers have consistently had the highest rate. Birth rates also vary geographically, with the highest rates of teen pregnancy in Arkansas (43.5) and New Mexico (43.3) and the lowest rate in Massachusetts (12.1) in 2013. Geographic rates generally reflect the racial, ethnic, and socioeconomic status of those living in the area.

Early childbearing is associated with educational disadvantages. Girls who become pregnant as teens are educationally behind their peers before the pregnancy, and girls with intellectual disability seem to be at particularly high risk for pregnancy. In addition, the educational aspirations of girls who bear children seem to be lower than those of their peers; such teens do not regard early pregnancy and parenting as undesirable life options. Other associations with pregnancy in teens include risk-taking behaviors; early initiation of sexual activity; family history of adolescent pregnancy in the mother or in siblings; and adverse childhood experiences such as abuse, exposure to violence, substance abuse, mental illness, criminal household member, and divorced or separated parents.

Fathers of infants born to teen mothers have the same backgrounds and many of the same characteristics as their partners, although many of the men are older and are legally adults. In most instances, male sexual partners are approximately 3 years older than their female partners, whatever their ages. In some racial and ethnic groups, the age difference between fathers and their teen partners may be greater than

average. Each state has its own definition of statutory rape, and some pregnancies clearly fit into this official category, although most teen mothers view their sexual activity as voluntary and consensual. The younger the pregnant teen, the greater the likelihood that the pregnancy is a result of either forced sex or statutory rape (perpetrators could be family members, caretakers, friends, dating partners, or strangers). In general, the men who father the infants of teen women are frequently from disadvantaged socioeconomic classes, are often educationally behind their peers, are more likely to have legal difficulties, are more likely to use illegal substances, and are more likely to acquire a sexually transmitted infection than age-matched peers. If they work, these men usually have lower-paying jobs than their age-matched peers. Many of these young men have mothers or sisters who were pregnant as adolescents. It also seems that having a teen father predisposes to becoming a teen father. These characteristics may not apply to young men whose pregnant partners choose to terminate their pregnancies.

## EVALUATION

### Physical Examination

Pregnant teenagers may not seek care for the classic symptoms of pregnancy, such as a missed menstrual period, morning nausea, and breast tenderness. Instead, teens may seek care for other physical complaints, some of which are entirely unrelated to pregnancy (eg, sore throat). Physicians who care for young women of childbearing age must always consider pregnancy, regardless of the symptoms the teen exhibits. The last menstrual period should be routinely determined and recorded at every office visit for a teenage girl, then noted by the nurse or other nonphysician before seeing the patient. The validity of the stated last menstrual period should be questioned if any clinical suspicion of pregnancy exists, and a urine or serum pregnancy test should be performed.

Pregnancy should always be considered in a young woman who has secondary amenorrhea. Other symptoms that suggest pregnancy are fatigue, nausea (particularly nausea that is relieved by eating), dizziness or syncope, urinary frequency, weight gain, breast tenderness or enlargement, and abdominal tenderness or enlargement.

Pelvic and breast examinations may be performed to confirm the diagnosis. Breast fullness and tenderness may be noted. Uterine enlargement varies with the gestational age of the pregnancy (Box 122-1). In addition, the physician may note cervical softening and cyanosis during the pelvic examination during early pregnancy. A pregnancy test should be performed in these cases.

### Laboratory Evaluation

Currently available urine pregnancy tests, most of which use enzyme-linked immunosorbent assay techniques and monoclonal antibodies to human chorionic gonadotropin (hCG), are sensitive and are able to detect pregnancy as early as 3 to 3.5 weeks after the last menstrual period (1–1.5 weeks after ovulation in a

### BOX 122-1 Uterine Changes With Pregnancy

- 4 weeks: Cervical softening and cyanosis is noted.
- 8 weeks: Uterus is the size of an orange.
- 12 weeks: Uterus is grapefruit sized and palpable suprapubically.
- 20 weeks: Uterus is at the umbilicus.

woman with 28-day cycles), although they are more accurate at 4 to 4.5 weeks because the low level of hCG seen during the first week of gestation is at the lower level of detection and may be missed. These tests are easy to perform in an office setting. Serum hCG determination can be performed if any question exists of urine tampering, inaccurate urinary hCG, spontaneous or threatened abortion, or ectopic pregnancy.

### Imaging Studies

If the dating of the pregnancy is in question, or suspicion of an abnormal pregnancy exists, then a pelvic ultrasound may be useful. Pelvic ultrasound performed transabdominally can detect a gestational sac as early as 5 to 6 weeks after the last menstrual period. If the ultrasound is performed transvaginally, then a gestational sac may be determined as early as 4 to 5 weeks' gestation.

## MANAGEMENT

Once a teen pregnancy has been confirmed, several complicated issues need to be addressed with the patient. To address these issues appropriately, physicians must be familiar with the pertinent laws of the state in which they are practicing, with their local school system's policies in dealing with pregnant teens and teen parents, and with local medical, financial, and social resources. Prenatal care may be provided by a teen-friendly physician, by a publicly funded clinic (some of which have extra expertise in caring for teens), or by a university clinic. It is important for the pediatrician to help the teen choose an obstetric provider who will provide the most supportive environment locally and financially possible. Many teens will need additional educational, social, and financial supports for optimal care during the pregnancy and during childrearing. Box 122-2 lists the ways a primary care physician can help the pregnant teenager.

The teen must first be privately informed of her pregnancy. Her reaction will depend on several factors—whether the pregnancy was suspected or not suspected, wanted or unwanted, planned or unplanned. Next, a determination must be made as to whether informing the patient's parents and the father of the child will cause any difficulties, and then the patient must be helped to address the difficulties. The age of the father of the baby and the teen's relationship to the father should always be asked to determine whether the physician should inform local authorities of abuse or statutory rape (see Chapter 371, Rape, for

**BOX 122-2 How a Primary Care Physician Can Help a Pregnant Teenager**

- Help the teenager think through her options for the pregnancy.
- Facilitate an appointment for prenatal care.
- Help the teen's parents cope with the pregnancy.
- Facilitate the teen's return to school.

more information). In addition, the patient should be helped to understand the social, emotional, educational, and financial implications of the pregnancy. Addressing all of these issues may require referral of the patient to an outside counselor such as a social worker skilled in these issues, or several office visits for a patient with few other resources.

All patients should be presented with the options legally available to them: abortion, adoption, or parenthood. Some pregnant teens will decide that they are not ready to parent, and they may decide to terminate the pregnancy or to make a plan for adoption. Physicians who have moral or religious objections to discussing these issues should refer their patients to other physicians who can support the possible patient choices. Patient coercion of any kind in this matter is not appropriate professional behavior. Primary care physicians should refer patients who choose termination to the appropriate local resources. Patients who choose adoption should be referred to agencies that have policies in place to safeguard the rights of the pregnant mother, her infant, the father of the baby, and the prospective parents. Teens who choose to terminate the pregnancy and those who opt for adoption may continue to need emotional support from their primary care physician or their counselor, just as the young mother who decides to parent will.

Although the social aspects of the pregnancy are addressed, and although the patient is awaiting her first obstetric visit with a physician who is knowledgeable about and accepting of teenage pregnancy, the primary care physician must be sure that the young mother has no disorders that might constitute a risk to herself or her unborn child and that she can appropriately care for herself during her pregnancy. In addition, the risk for violence to the young mother should be determined. Baseline height, weight, and blood pressure should be obtained. Screening for human immunodeficiency virus, syphilis, chlamydia, gonorrhea, bacterial vaginosis, and *Trichomonas* should be carried out, and treatment should be initiated as appropriate. The adolescent should be counseled about proper nutrition and rest; she should also be encouraged to avoid exposure to tobacco, alcohol, and drugs, including both drugs of abuse and excessive over-the-counter medications. Any medications taken for chronic illnesses should be reviewed for teratogenic potential. Prenatal vitamins should be prescribed. Tdap and influenza vaccines should be provided as recommended by the American Academy of Pediatrics Committee on Infectious Diseases in the *Red Book*.

**OUTCOMES**

Pregnancy outcomes in teens include not only the physical outcomes to mother and child but also the social, educational, emotional, and financial outcomes for everyone affected by the pregnancy. An abundance of information exists regarding infants' and mothers' health, but the lives of the infant's father, grandparents, and other family members will also be affected.

The physical outcomes of pregnancies in teenagers are generally good. However, very young mothers are at increased risk for toxemia of pregnancy, maternal anemia, infant death, prematurity, and low-birth-weight infants. Many of these effects seem to be ameliorated by early prenatal care and appropriate maternal weight gain. Although poor outcomes are influenced by the lower socioeconomic status of the adolescent mother, age itself may be a moderating factor as well. Adolescent mothers generally do well in labor and recover easily from the effects of childbirth.

Other risk factors exist for the adolescent mother. One short-term concern is violence. Pregnant teens seem to be at increased risk for becoming victims of family or intimate partner violence. Another short-term concern is depression; postpartum adolescents seem to be at higher risk than their adult counterparts, although this may be ameliorated by the presence of social supports from the teen's mother and from the father of the infant. Women who become pregnant during adolescence also seem to have a higher than normal long-term risk for depression and other emotional difficulties. In addition, although most women who become pregnant as teenagers eventually complete their high school education, they continue to remain educationally behind their age-matched peers; many of their peers elect participation in post-high school training, and teen mothers are less likely to do so. Only two-thirds of teen mothers receive their GED or high school diploma by age 22, compared with 94% of those who did not give birth as teens. Mothers who live with the father of their infant or who do not return to school to complete their education are most likely to have a repeat pregnancy soon after the first. The second pregnancy is more likely to end in elective termination than the first. If it does not, then the mother frequently enters into prenatal care later than she did with her first infant, and the second infant is at greater risk for low birth weight. The second infant is also at greater risk for death by homicide, with the mother's current boyfriend (not the infant's father) being the most common perpetrator. Marriages formed in response to pregnancy generally fail with time, leaving the young mother with children and few resources for their support. These issues clearly produce significant financial implications for the young mother, her children, and society. Clinics specializing in the care of pregnant adolescents have been shown to improve the outcomes of pregnancy, reduce premature delivery, and reduce subsequent teenage pregnancies.

For the child born to a teen mother, the long- and short-term effects of the mother's lower educational status, lower financial status, developmental immaturity, emotional stress, and adverse environment are

### BOX 122-3 How a Primary Care Physician Can Help a Teen Mother and Her Infant

- Teach the teen mother normal child development.
- Help the teen mother use positive parenting.
- Discuss ways to improve infant safety.
- Watch closely for postpartum depression.
- Encourage contraceptive use.
- Teach the infant's grandmother modern childrearing concepts.
- Help the father feel welcome at well-baby visits.
- Encourage the young mother to continue her education.
- Refer the family to support services as needed.
- Watch for behavioral and school problems in the child.

significant. Many adolescent mothers seem to lack knowledge of normal infant behavior, misinterpreting infant behavior as indicating that their child is more capable than is the case. They also seem to offer less infant stimulation than older mothers and to use harsher methods of discipline. The higher than normal rate of postpartum depression in teen mothers may influence maternal-child bonding and the amount of energy that the developmentally immature mother is able to put into guiding and teaching her infant. Infants of teenage mothers also seem to have an increased risk for abuse and neglect, although this seems to be related to family stress, socioeconomic circumstances, and the presence of a new boyfriend in the mother's life. Children born to teen mothers seem to have a higher than normal incidence of early behavior problems and to be less secure in their maternal-child bond than their peers. They also have higher rates of school failure, legal difficulties, and adolescent parenthood than their age-matched peers. The children of adult women who are prior teen mothers seem to be at excessive risk for poverty, death, poor educational outcomes, and involvement with state-sponsored family services programs. Some of the problems teen mothers encounter with parenthood can be addressed by providing social supports such as visiting nurses on a regular basis. Box 122-3 lists ways to help a teen mother.

## PREVENTION

Physicians can facilitate pregnancy prevention by routinely providing education about risks and prevention methods to all pubertal patients. Many teens who become pregnant seem not to have understood their actual risk at the time of conception. However, prevention seems to require more than education and readily available contraception. Facilitating parent-child discussions about sexuality and childbearing may also be an effective strategy, as may teaching negotiation skills for pregnancy prevention. Community programs, particularly those that foster positive youth development, may be an effective adjunct.

Effective programs need to identify specific youth at greatest risk—school dropouts, risk takers, delinquents—and concentrate their efforts on these individuals. Much has been learned about the prevention of adolescent pregnancy in the past 40 years, and clearly no sole program is appropriate for all communities or for all teens and their families. However, some characteristics are common to most successful programs. These characteristics include:

1. A focus on specific behavioral goals
2. A program based on theoretical approaches
3. Delivering clear messages about sexual activity and contraceptive use
4. Providing basic information about risks associated with teen sexual activity
5. Addressing social pressure to have sex
6. Providing activities to practice communication and refusal skills
7. Incorporating multiple teaching methods
8. Tailoring the program to participants' age, culture, and level of sexual experience
9. Providing an appropriate length of time to cover all the activities
10. Providing appropriate training for teachers or peer leaders who are involved in the program

Programs to reduce repeat births (secondary prevention) need a different emphasis than the programs for primary prevention (preventing the first birth). Successful secondary prevention programs require effective personnel who maintain close, sustained relationships with teen mothers with an emphasis on school completion and family planning. Regardless of the type of program developed for secondary prevention, physicians should always remember that the pregnant teenager is an adolescent who happens to be pregnant, not a pregnant woman who happens to be an adolescent.

**Chapter 123****CONTRACEPTION AND ABORTION**

Eric Schaff, MD

In 2009, the number of 15- to 19-year-old female adolescents in the United States was approximately 10 million, of which approximately 750,000 became pregnant; one-half of these pregnancies resulted in births, one-third resulted in abortions, and the remaining were failed pregnancies. Although the rate of unintended pregnancies in the United States continues to decline slowly, it is higher than that in most developed countries. In 2013, the total teen pregnancy births dropped an additional 10% from 2012, to 273,000, the

lowest level reported to date. An estimated one-third of teens will experience a pregnancy by age 20. The Healthy People 2020 Objectives established by the US Department of Health and Human Services include the goal of reducing adolescent pregnancies by increasing the percent of females or their partners who used contraception at their most recent intercourse to 92% (up from 83% from 2010 findings).

An unintended pregnancy can have significant medical, social, and financial consequences for an unprepared teen, her family, and the community. The American Academy of Pediatrics, American College of Obstetrics and Gynecology, and American Medical Association's *Guidelines for Adolescent Preventive Services* have recommendations for physicians caring for teens that include routine screening for sexual activity, support for sexual abstinence, the need for contraception, and the importance of counseling about the risks of unintended pregnancy or a sexually transmitted infection (STI). The National Campaign to Prevent Teenage Pregnancy in "No Easy Answers: Research Findings on Programs to Reduce Teen Pregnancy" found that no single strategy reduces teen pregnancy rates significantly. Approaches should target both abstinent and sexually active youth.

Physicians are particularly attuned to preventive public health measures that decrease morbidity and decrease costs. Physicians play an important role in preventing unintended pregnancies by ensuring access to contraceptive methods and emergency contraception for sexually active teens. Physicians, knowing that most older teens do become sexually active at some point, should encourage normal, healthy sexual development by assessing an adolescent's readiness to become involved in relationships that may lead to sexual activity. Teenagers who wish to wait and abstain from sex need encouragement and reassurance, emphasizing that abstinence is normal, is prevalent, and prevents both pregnancy and STIs. Youths who desire to become sexually active or who are already sexually active should be encouraged to use contraception, to know their partner's and their own STI screening status, and to limit the number of sexual contacts. In querying youth, the physician can better assess and address the context of the adolescent's sexual relationships (healthy or not) and provide appropriate counseling and services. Physicians should also be aware that intimate partner violence is, unfortunately, common in adolescents and may be either physical, emotional, or sexual. Because intimate partner violence may have profound effects on contraception behavior and risk for acquiring an STI, physicians should screen for safe relationships.

The rights of teens to receive different types of health care without parental consent vary widely among states. These situations include emergency medical care, reproductive health services, the emancipated minor, and the mature minor. To be emancipated, an adolescent must generally be of a state-defined minimal age (often 16 years), live apart from her parents, and be economically self-sufficient. Emancipation includes teens who are married, parenting, or serving in the military.

Although parental involvement in minors' reproductive decisions may be helpful and is ideally desirable, some adolescents will not seek services if they are required to inform their parents. Under the federal Health Insurance Portability and Accountability Act, physicians must follow state guidelines for confidentiality and may require the consent of the adolescent before releasing information to anyone, including her parents.

The benefits of contraceptive services typically outweigh any medical risks. The long-acting intrauterine device (IUD) and the 3-year progestin subdermal implant rod are gaining increasing favor, and the 3-month progesterone injection continues to be popular. Condoms continue to be a mainstay for STI prevention. More emergency contraceptive options are emerging.

Significant advances have been made in early abortion services. Detection of early pregnancy has been simplified by inexpensive home and office pregnancy tests that are positive 4 weeks after the last menstrual period. Earlier and more accurate pregnancy dating starting about 5 weeks from the last menstrual period is now possible through vaginal probe sonography. Earlier and safer abortion procedures are now available with the medical abortion pill mifepristone, and with suction abortion.

This chapter provides information basic to the physician's task of providing reproductive health care to teenagers.

## CONTRACEPTION

Two methods are used to describe the effectiveness of contraception to prevent pregnancy: typical use rate and perfect use rate. Typical use rate refers to the effectiveness of a method when used by the average woman (ie, not using the method correctly or every time). Perfect use rate refers to the ability of the method to prevent pregnancy when the method is used perfectly (ie, according to manufacturer's directions and every time required).

In general, all contraceptive methods are highly effective when used correctly, and, in all healthy women, their benefits far outweigh their health risks. When considering a contraceptive method, the short- and long-term medical risks and financial costs should also be compared with the risks and costs associated with not using the method, that is, an unintended pregnancy.

In the past, a physical examination that included breast and pelvic examinations was accepted practice before prescribing hormonal contraception. These examinations have not been found to affect prescribing and may be feared and avoided by teens, thereby being a barrier to highly effective contraceptive methods. Expert medical opinion has shifted away from requiring a general examination that includes breast and pelvic examinations before initiating hormonal contraception. Of note, breast cancer is rare in women younger than 30 years of age. The US Preventive Services Task Force recommends breast cancer screening with mammography, with or without clinical breast examination, starting at age 40.

Unrelated to contraception, sexually active female teens should be screened yearly for chlamydia and, if the community prevalence is high, both females and

males should be screened for gonorrhea. A significant advance, especially for pediatric practices that are not prepared for pelvic examinations or male penile cultures, is the screening for chlamydia and gonorrhea by urine testing.

Cervical cancer screening with either Papanicolaou tests or liquid cytologic assessment should also not be directly tied to hormonal contraceptive provision. Current cervical screening guidelines recommend starting at age 21 because most cervical dysplasia reverts back to normal, aggressive treatment can have negative consequences, and progression takes years.

## Hormonal Methods

Hormonal methods of contraception involve using either combined synthetic estrogen and progestin (combined oral contraceptive pills, transdermal patch, and vaginal ring) or progestin-only products (progesterone-only pills, 3-month injection, 3-year subdermal implant, and 3- and 5-year progestin IUD). Although progesterones are sufficient and necessary for contraception, estrogens help to regulate the menstrual cycle. As a group, these methods have many features in common that include their mechanism of action, effectiveness, advantages, disadvantages, and side effects. To a varying degree, these methods prevent pregnancy by 3 main mechanisms: suppressing luteinizing and follicle-stimulating hormones, thereby inhibiting ovulation; thickening cervical mucus, making it less penetrable by sperm; and altering the endometrium, making it less receptive to implantation of a fertilized ovum. When hormonal methods begin within 5 days of the onset of a normal menses, ovulation is usually suppressed, thereby preventing pregnancy. When used correctly, these methods are 99% effective in preventing pregnancy, and ovulation returns quickly when stopped (except for intramuscular progesterone, which often delays ovulation beyond 3 months).

While using combined hormonal contraception, menses are usually regular, shorter in duration, sometimes absent, and avoided altogether for convenience by skipping the hormone-free time period between active ingredients. These methods are also associated with less dysmenorrhea, acne, benign fibrocystic breast disease, pelvic inflammatory disease (because of thickened cervical mucus that blocks ascending infection), and ovarian and endometrial cancer. Women who use an oral contraceptive pill (OCP) for as little as 6 to 12 months experienced a 40% reduction in the risk for ovarian cancer, and long-term OCP users (>10 years) experienced an 80% reduction. No evidence has been found that OCPs increase mortality from breast cancer, even with prolonged use.

Before prescribing estrogen-containing hormonal contraception, the physician should be certain that there are no contraindications to their use, which are very few. In general, healthy teens are excellent candidates for hormonal contraceptives. A summary of the recommendations by the World Health Organization for prescribing estrogen-containing hormonal contraception is noted in Box 123-1. Combined hormonal contraception can safely be provided based on a negative medical history for contraindications and a blood pressure measurement within normal limits.

### BOX 123-1 World Health Organization Contraindications and Precautions for Prescribing Estrogen-Related Hormonal Contraception

#### NO CONTRAINDICATIONS

- Mild headaches
- Benign breast disease
- Obesity
- Pelvic inflammatory disease
- Thyroid disorders
- Epilepsy
- Iron-deficiency anemia
- Use of antibiotics
- Dysmenorrhea
- Endometriosis
- HIV
- Viral hepatitis carrier
- Irregular menstrual bleeding
- History of ectopic pregnancy
- History of gestational diabetes
- Family history of breast cancer
- Gestational trophoblastic disease (benign or malignant)
- Benign ovarian tumors

#### CAUTION ADVISED

- Hyperlipidemia
- Less than 21 days postpartum
- Breastfeeding from 6 weeks to 6 months postpartum using medications that affect liver enzymes (eg, rifampin, griseofulvin, phenytoin, carbamazepine, barbiturates, primidone)
- Undergoing major surgery with prolonged immobilization
- Unexplained vaginal bleeding

#### CONTRAINDICATIONS

- Pregnancy
- Hypertension
- Certain heart and liver diseases
- Diabetes mellitus when either longstanding or with end-organ involvement
- History of thromboembolic disease or stroke
- Migraine headaches with focal, neurologic symptoms
- Less than 6 weeks postpartum and breastfeeding

To improve access to care and adherence with contraception, pediatricians need to ensure confidentiality. They must also assess their patient's understanding of the benefits, risks, and alternatives of the chosen method; their concerns about becoming pregnant; and their motivation to use the method selected. Counseling and handouts are key to supporting teens dealing with or anticipating minor side effects, such as breakthrough vaginal bleeding, nausea, headaches, bloating, mood changes, and irritability, all of which are likely to resolve after several menstrual cycles. Many of these side effects may be unrelated to contraception but rather the usual stresses in a teen's life. Weight gain caused by an increase in appetite

while on hormonal contraception can be countered by good eating habits and regular exercise. Persistent mood changes or depression will require stopping the hormonal method for further evaluation. Although effective at preventing pregnancy, these methods do not protect against STIs, and therefore the use of condoms must always be encouraged for teens at risk for STIs.

### Combined Estrogen/Progestin Methods

**ORAL CONTRACEPTIVES.** Oral contraceptive pills are one of the most popular methods of birth control used by young women. Unfortunately, adherence continues to be a concern, and more than one-half of teens will discontinue their OCP during the first year of use.

All low-dose combination pills consist of only a single estrogen, ethinyl estradiol, with the dose ranging from 10 to 35 mcg/day, and one of many different synthetic progestins derived from estranes, gonanes, or an unclassified group. Estranes were marketed first and consist of norethindrone or compounds that convert to norethindrone. Gonanes consist of norgestrel, levonorgestrel, norgestimate, and desogestrel. The latter 2 agents are newer and have the advantage of being potent progestins but producing fewer androgenic side effects. Norgestimate and desogestrel also increase high-density lipoprotein, which is protective against atherosclerosis, and have a slightly longer half-life that makes vaginal spotting and pregnancy less likely if a woman forgets to take her daily pill. An unclassified progestin is drospirenone derived from spironolactone and has antimineralocorticoid properties with fewer premenstrual bloating symptoms and mild antiandrogenic activity. There is no difference in effectiveness in pregnancy prevention among the different OCPs.

The disadvantages of OCPs include the need for daily use, theoretical decreased effectiveness caused by some antibiotics (eg, rifampin, doxycycline) and antiseizure medications (eg, phenobarbital and phenytoin), and increased risk for rare venous thromboembolic disease.

The risk for venous thromboembolism for healthy teenagers not using hormonal contraception is very low, approximately 3 per 100,000 women. The risk increases to 7 to 10 per 100,000 when using combined oral contraceptives. To decrease the risk, the doses of synthetic estrogens have decreased significantly since the original pill formulations. The risk should be compared with the greater risk for thromboembolism in pregnancy. Some confusion exists in attempting to quantify the exact risk attributed to different birth control pills because these adverse events are rare and the studies are not randomized but postmarket observations. Newer methods may seem to have higher risk for thromboembolism than older methods because of a bias to prescribe the newest and lowest-dose oral contraceptives to women not tolerating older OCPs and women at possible higher risk for medical complications.

Considerable flexibility exists regarding which brand of OCP to prescribe. Most commonly, a 28-day-cycle pack (21 days of active hormones and 7 days of placebo) is used. Despite claims by manufacturers, clinical differences among brands of low-dose pills are minimal

regardless of whether the hormones are fixed (monophasic) or varied (biphasic or triphasic) throughout the month. The lowest dose estrogen pills may not provide the best cycle control and mid cycle spotting may occur which, in turn, may decrease compliance. Physicians can choose any one of the following strategies in prescribing oral contraceptives: an inexpensive generic brand, a low-estrogen preparation containing 10 to 25 mcg of ethinyl estradiol, a 30- to 35-mcg pill that has less intermenstrual spotting, an older progestin with low androgenicity such as norethindrone, or a new-generation progestin that has a longer half-life but also low androgenic effects (norgestimate or drospirenone). Pills containing desogestrel have a small increased risk (1.5 to 2.7 times) for venous thromboembolism.

To improve adherence, the physician should prescribe a sufficient number of packs to prevent running out of pills. The first few months should serve to identify any health concerns or problems the teen may identify in taking the pills. After this initial prescription, 12-month supplies can be prescribed to increase adherence.

OCPs can be started on day 5 after the start of menses, on the Sunday after menstrual bleeding starts (Sunday start), or by the “quick-start” method. Quick-start allows hormonal methods to be started on any day if the physician is reasonably certain that the teenager is not pregnant; for example, she has not had sex since her last normal menses or has been using another birth control method correctly and every time. For quick-start, if more than 5 days have elapsed since the menses started, then the teenager needs to abstain from sex or use additional contraceptive protection such as condoms for the next 7 days. These 3 options ensure that the teen is not pregnant and should suppress ovulation during the first cycle (except for the quick-start method).

The pill should be taken at the same time each day. Taking it before bedtime allows for the peak concentration of the hormones to occur during sleep, thereby masking some symptoms such as nausea. If 1 pill is forgotten (particularly during the first 7 days that are needed to suppress ovulation), then it should be taken as soon as it is remembered. If 2 or 3 pills are missed, and if there was no unprotected intercourse in the last 5 days, then the teenager should take 2 active pills all at once, use back-up method for the next 7 days, and finish the pill pack by taking 1 pill daily. If there was unprotected intercourse in the last 5 days, then the teenager should be instructed to use emergency contraception today, restart the active pills the next day, and use a back-up method for 7 days. If 4 pills are missed, and if there was no unprotected intercourse in the last 5 days, the teenager should use a back-up method for the next 7 days and finish the pill pack by taking 1 pill daily, skip the 7 placebo pills, and immediately start the next pack. If there was unprotected intercourse in the last 5 days, she should use emergency contraception today, restart the active pills the next day, skip the 7 placebo pills, immediately start the next pack, and use a back-up method for 7 days. Withdrawal bleeding is common 2 or 3 days after the last pill is taken.

If mild side effects do not resolve after several cycles of a particular OCP, then the brand can be changed to another containing a different amount of estrogen or a different progestin. If menstruation does not occur, the pills should be continued and a pregnancy test obtained for reassurance and to detect the rare pregnancy.

Use of extended-cycle oral contraceptives of 84 days or continuous-cycle of 365 days of active pills reduces the number of menses from 13 to only 4 or 1 per year. All of the combined estrogen/progesterone methods can become extended-cycle by avoiding the week of placebo or no medication for 2 out of 3 cycles. Theoretically, a chance ovulation is less likely to occur because follicles have less chance of maturing during the pill-free week when on monthly OCPs. Extended-cycle products may be of benefit for teens who prefer to have fewer menses or who have a history of menorrhagia, menstrual migraine, difficulty with regulating other long-term medications affected by the changes of hormones during the pill-free week, and endometriosis. Breakthrough bleeding may be encountered.

**TRANSDERMAL PATCH AND VAGINAL RING.** Newer methods that change the route of administration of hormones and do not require daily use show improved adherence and higher typical use effectiveness rates. These methods include the weekly transdermal patch and the monthly vaginal contraceptive ring.

The transdermal patch (Ortho Evra) has the advantage of once-weekly application. This product contains 0.75 mg ethinyl estradiol and 6 mg norelgestromin, the active metabolite of norgestimate. The patch is worn weekly for 3 consecutive weeks; the fourth week is patch free, allowing for withdrawal bleeding. The patch may be applied to the abdomen, buttocks, upper outer arm, or upper torso (excluding breasts). Clinical trials suggest that the transdermal patch is less effective in women weighing more than 198 lb (90 kg). The average serum concentration of ethinyl estradiol (area under the curve) is approximately 60% higher than oral contraceptives, although the clinical significance and risk for thromboembolic disease are unknown. The patch must be adherent to the skin and cannot be off for more than 24 hours. If these conditions do not hold, a back-up method should be used for that week until another patch is applied.

The vaginal ring (NuvaRing) is a combination of 2.7 mg ethinyl estradiol and 11.7 mg etonogestrel that delivers a daily dose of 15 mcg and 0.12 mg, respectively. The ring consists of a flexible plastic ring of ethylene vinyl acetate and is available in one size (2 inches in diameter and 1/8-inch thick). Because the ring is “one size fits all,” it requires no specific placement techniques. The ring should be placed in the vagina within the first 5 days of the menstrual cycle and remain in place for 3 consecutive weeks. It is then removed and discarded. A new ring is inserted after 7 days, allowing for withdrawal bleeding. If the user and her partner prefer, the ring may be removed for intercourse as long as it is replaced within 2 to 3 hours. However, if the ring is left out for more than 3 hours, then she can reinsert the ring but must either abstain from sex or use a condom for the next 7 days.

### Progestin-Only Methods

The progestin-only methods (progestin-only oral contraceptives, 3-month injectable depo-medroxyprogesterone acetate, 3-year subdermal rod implant, and progestin-IUD) are not associated with venous thromboembolic events. Therefore, these methods are indicated for women with a contraindication to estrogen or preferred because of their inherent properties. These methods are associated with more irregular vaginal bleeding than combined hormonal methods.

#### PROGESTIN-ONLY ORAL CONTRACEPTIVES.

Progestin-only OCPs, also known as mini-pills, contain a low dose of a progestin (norethindrone). They have the same mechanism of action as combined estrogen/progestin pills. They are taken for 28 days with no break between packs and need to be taken at the same time each day.

#### THREE-MONTH DEPO-MEDROXYPROGESTERONE ACETATE INJECTION.

A highly effective and popular method is the 3-month injectable progestin, depo-medroxyprogesterone acetate (DMPA; Depo-Provera) injection. As many as 10% to 15% of teens report using DMPA. Each 150-mg injection provides 12 weeks of effective contraceptive protection plus an additional 2-week grace period (for a total of 14 weeks). It requires vigorous shaking to suspend all the particles and is given deep intramuscularly in either the deltoid or upper outer quadrant of the gluteal muscle. The site should not be massaged because the rate of absorption and metabolism may be increased, thereby decreasing effectiveness. A generic product is available that reduces the cost. DMPA is also known to stimulate appetite and can lead to weight gain if calories are increased.

A new route of medroxyprogesterone acetate is subcutaneous administration, the same used for insulin injections. This 104-mg dose can be given at home if the teen or a support person can be taught how to give the injection, thereby avoiding an office visit.

The advantages of the progesterone-only injection include long-acting protection; avoidance of estrogen and its risk for venous thromboembolism; lack of interference with breastfeeding; possible reduction in both the incidence of seizures and the painful hemolytic crisis of teens with sickle cell disease; continued contraceptive effectiveness when using antibiotics or antiseizure medicines; and thinning of the endometrium, causing amenorrhea in up to 50% of women after the first year and an even higher percentage of women thereafter. The disadvantages of this injection include the need for repeated injections every 3 months; a hypoestrogen state that causes a reversible decrease in bone density, though significantly less than pregnancy; and a delay in clearance of DMPA for as long as 12 months, resulting in reduced fertility after discontinuation. Decreased bone mineral density has been shown to be reversible and should not be a reason to discontinue use.

Irregular or prolonged bleeding while on DMPA is common in the first year. Managing side effects is important in supporting continued use of injectable progesterone. Vaginal bleeding can be managed by offering 14 to 28 days of conjugated estrogen 0.625 mg, estradiol 1 mg, or a cycle of combined OCPs.

**THREE-YEAR SUBDERMAL ROD IMPLANT.** A subdermal implantable hormonal contraceptive (Implanon) is highly effective at providing low-dose, continuous contraception for up to 3 years. It involves only the progesterone etonogestrel within a rod of ethylene vinyl acetate. (Both components are also used with the vaginal ring.) Etonogestrel is the active metabolite of desogestrel, a progestin in oral contraceptives. With training, insertion and removal under local anesthesia with 1% lidocaine are easy skills to learn.

The advantages of the implantable rod include its long-acting protection; avoidance of estrogen and therefore venous thromboembolic disease; low dose of progestin, allowing for continuous endogenous estrogen production and thereby not affecting bone demineralization; and quick reversibility. The major disadvantages of this method include the unpredictability of menstrual patterns, the cost, and the need for a minor procedure.

**THREE- AND FIVE-YEAR PROGESTIN INTRAUTERINE DEVICE.** See the section on intrauterine devices.

### Emergency Contraception

An emergency contraception pill (ECP) prevents pregnancy after unprotected intercourse and may also be referred to as a *postcoital* or *morning-after* pill. They consist of a single dose of 1.5 mg of the oral progestin levonorgestrel. An alternative, older method is possible by taking an equivalent dose of levonorgestrel or norgestrel from 4 or 5 combined low-dose pills and repeating 12 hours later.

ECPs are indicated when other methods fail, when no contraception is used, or when rape occurs. They are available over the counter for women aged 17 years and older. One strategy to increase access to an ECP for sexually active teens younger than 17 years is to give them a prescription in anticipation of unprotected intercourse.

ECPs reduce the risk for pregnancy by about 88%. For example, if 100 women have unprotected intercourse in the second or third week of their cycle, 8 will become pregnant without ECPs, but 1 will become pregnant using progestin-only ECPs, an 88% reduction. If a current pregnancy is possible, then a pregnancy test should be performed before taking ECPs, though taking them has not been known to harm an established pregnancy. A nationwide hotline (800-NOT-2-LATE) and Web site ([ec.princeton.edu](http://ec.princeton.edu)) are available to increase public awareness of emergency contraception.

High-dose levonorgestrel (Plan B One Step or generic) should be taken as soon as possible after unprotected intercourse for greatest effectiveness, but can be used up to 5 days later. Nausea and, rarely, vomiting can occur and may require anti-nausea treatment. Breast tenderness, irregular bleeding, fluid retention, and headaches rarely occur. For ongoing contraception, hormonal contraceptives can be started on the first Sunday after the onset of the next menstrual period or the same day as the ECP (quick-start method) with 7 days of condom use. If the next menses is delayed, then the teen should be instructed to return for a pregnancy test.

A progesterone agonist/antagonist (Ella) is approved by the US Food and Drug Administration for emergency contraception within 5 days of unprotected intercourse.

## Barrier Methods

### Condoms

Throughout the world, condom use has increased significantly because of social marketing campaigns addressing the human immunodeficiency virus (HIV) epidemic. Latex condoms work by containing the ejaculate and are effective in pregnancy prevention and in reducing the spread of all STIs, including HIV. Making condoms readily available increases their use. Even if teens prefer a hormonal birth control as their primary method for preventing pregnancy, they should be encouraged to use condoms if they are at risk for STIs.

Condoms are inexpensive, available over the counter, a means to involve the male in sharing responsibility for contraception, lubricated for comfort, associated with minimal side effects, and simple to use. The disadvantages of condoms are the diminished genital sensation noted by some individuals and the lack of 100% protection against STIs.

Lubricated (but not nonoxynol-9) latex condoms offer the best protection. Condoms should be placed on the erect penis before sex. To prevent condom breakage, condoms should not be stored in warm places (eg, a wallet) for long periods, lubricated with oil-based lubricants such as Vaseline, or reused. Polyurethane condoms, an alternative, are more expensive, but are stronger and thinner than latex condoms, odorless, and compatible with oil-based lubricants.

To prevent accidental spillage, teens should be instructed that the condom be removed shortly after ejaculation while holding the rim of the condom on the base of the penis. If spillage occurs or a condom breaks, then the penis and vagina should be washed with soap and water, spermicide used, and ECPs taken.

### Diaphragm and Female Condom

The diaphragm is a thin, rubber, 6.5- to 8-cm dome that is inserted into the vagina. It covers the cervix and blocks sperm from entering. It must be used with spermicidal contraceptive jelly, which has the active ingredient nonoxynol-9. When used correctly and consistently, the diaphragm's effectiveness can be quite high, although the typical use failure rate ranges from 6% to 16%. It also offers some protection from STIs and has minimal side effects. A diaphragm is a reasonable choice for a motivated teen who has contraindications or wants to avoid taking contraceptive hormones. The disadvantages of the diaphragm include the skill needed for placement, the need to leave it in place 6 hours after intercourse, the need for a second application of spermicidal jelly if intercourse is repeated after 6 hours, and the slight increase in vaginitis and urinary tract infections. Disadvantages for the physician include keeping a set of diaphragm rings for sizing and learning and maintaining the skill to fit a diaphragm when the requests are likely to be few.

The female condom is readily available without a prescription but is not widely used because of its high cost. It is made from polyurethane with 2 flexible polyurethane rings. One ring is placed inside the vagina to cover the cervix, similar to a diaphragm; the 2nd open ring remains on the outside of the perineum to protect against STIs. The female condom should not be used at the same time as latex condoms, nor should it be reused.

### Spermicidals: Vaginal Foam, Vaginal Sponge, and Vaginal Suppository

Vaginal foam, sponges, and suppositories contain nonoxynol-9, which has in vitro and in vivo protective properties against some STIs. These methods are relatively simple, effective, and inexpensive and can be obtained without a prescription. Spermicidals are important complementary methods when they are used with condoms, intercourse is infrequent, and they are used as a back-up method for other birth control methods.

The vaginal sponge, which is moistened with water before use, can be inserted several hours before intercourse and remains effective for 24 hours. Suppositories must be in the vagina at least 10 to 15 minutes before intercourse to allow them to dissolve.

### Natural Family Planning

Natural family planning methods identify the most fertile time during the menstrual cycle in order to avoid sexual intercourse. Methods include charting of menstrual cycles on the calendar to determine likely ovulation about 14 days before the next menses, recording basal body temperatures to document the rise of at least 0.4°C after ovulation, and monitoring the thinning of cervical mucus to detect when ovulation occurs. Advantages include the lack of side effects, acceptance by women opposed to hormonal and barrier methods, knowledge gained about reproductive physiology, and its practicality when barriers exist to accessing other methods. Disadvantages for teenagers include their irregular menstrual cycles, which make predicting ovulation difficult, the high degree of motivation required for effective use, and a 20% typical failure (pregnancy) rate.

### Intrauterine Device

There are 2 basic types of plastic IUDs available in the United States: one with a copper wire wrapping (Para-Gard) that lasts for 10 years and two containing the progestin levonorgestrel with either 52 mg that lasts for 5 years or a slightly smaller one with 13.5 mg that last for 3 years and being promoted for nulliparous women. Both types have a typical and perfect use rate of approximately 99% in preventing pregnancy. Once in place, the IUD requires no effort for continued effectiveness and has no additional costs. The mechanism of action is not clear but likely involves either causing a sterile inflammatory process of the endometrium, making it unsuitable for implantation of a fertilized egg; copper's toxic effects on enzymes that inhibit sperm migration; or additional atrophic endometrial changes from the progestin-containing IUD that also reduces menstrual bleeding. The IUD is indicated for

teens interested in highly effective, nonhormonal, long-term, and reversible contraception. It is also an appropriate choice for teens having difficulty with complying with other birth control methods or those who have serious medical conditions that would be worsened with a pregnancy.

The IUD has previously not been offered to teens because of the concern it might lead to fallopian tube scarring and infertility. Recent evidence-based studies have demonstrated the safety of IUDs for all age groups with recommendations that the benefits outweigh the risk. The IUD's monofilament strings do not interfere with protective properties of cervical mucus and the progestin-containing IUD thickens the cervical mucus and decreases menstrual flow or amenorrhea, all mechanisms that decrease the risk for pelvic inflammatory disease. A current or high risk for an STI is still a contraindication. Condoms are recommended for STI protection. Compared with other countries, the prevalence of IUD use in the United States is low, mainly because of its high initial costs.

The copper IUD allows for regular menstrual cycles, which can be heavier. Insertion can be easier during the menstrual cycle or after an abortion or pregnancy. Nulliparous women have a slightly higher rate of expulsion.

## ABORTION

More than one-third of pregnant teens in the United States choose abortion. The earlier the abortion is performed, the safer it is. Unfortunately, teens are more likely than older women to delay an abortion. The reasons cited most often by teens for choosing an abortion are how a baby will negatively affect their lives, financial concerns, and feeling that they are not mature enough to have a child.

Most young teenagers involve their parents in these decisions. Some states require parental consent or notification for a minor to obtain an abortion. In these states, a minor who does not want to involve her parents must be able to obtain a judicial or administrative bypass.

### Suction Curettage

Surgical (suction) abortion is greater than 99% effective and has an excellent safety record of approximately 1 death per 1 million early first-trimester procedures. Women receive local anesthesia and may have the choice of additional medication to relieve pain or anxiety by mouth or IV sedation. Unfortunately, mortality rates remain high in developing countries where a need exists for safe, legal, and accessible abortion services.

Rare complications of abortion can include excessive bleeding, infection, perforation of the uterus, and adverse anesthetic events. A prophylactic antibiotic is recommended following the procedure.

### Medical Abortion

Mifepristone (Mifeprex, formerly known as RU 486, the *French abortion pill*), available in more than 2 dozen countries since 1988, was approved in the United States in 2000. Mifepristone blocks the action of progesterone,

which causes the pregnancy to separate from the endometrium and sensitizes the uterus to the uterotonic effects of a synthetic prostaglandin. The second required medication, misoprostol, is the synthetic prostaglandin given 1 to 2 days later, which causes the uterus to contract and the pregnancy to be expelled. The prescribing physician must be able to confirm that the gestational age is no greater than 7 weeks, to make sure it is not an ectopic pregnancy, and to perform or refer for a surgical abortion if needed. Because of the high cost of mifepristone, evidence-based regimens in the United States have been developed that use a lower dose of mifepristone, require a higher dose of misoprostol taken either buccally or vaginally, and are effective up to 9 weeks of pregnancy, depending on the regimen. A prophylactic antibiotic is often recommended, as with suction abortion.

Approximately 2% to 5% of women will need an aspiration curettage for a continuing pregnancy or persistent or heavy bleeding.

The major advantages of a medical abortion include its early use in pregnancy; avoidance of a surgical procedure; and perception of being more natural, less invasive, and private. Disadvantages of medical abortion include the length of time involved from initiation to final confirmation; potential side effects of nausea, vomiting, and diarrhea from misoprostol; cramping; unexpected heavy or persistent bleeding requiring suction curettage; continuing pregnancies requiring suction curettage in less than 1% of women; and the serious infections from *Clostridium* species (*C. sordellii*) that have a mortality rate of approximately 1 per 100,000 medical abortions, found at a similar rate as a spontaneous miscarriage.

## SUMMARY

Teens need to be encouraged to develop healthy relationships, regardless of whether they elect to be sexually active or not. Physicians should offer encouragement to those who choose abstinence, as well as identify those who are ready to become or already are sexually active, and help them make informed decisions about pregnancy prevention and STI protection. Current contraceptive methods are highly effective and safe. Hormonal methods have important noncontraceptive benefits such as regulated menses, reduced dysmenorrhea, and reduced risks for endometrial and ovarian cancer. Easy access to emergency contraception is an important back-up method to reduce unintended pregnancies and can be prescribed in advance at pediatric visits or is available over the counter for those older than 16 years of age. Early abortion should be readily available with minimal obstacles because of its safety over delayed abortions. Mifepristone is an important alternative to suction abortion for teens fearful of a surgical procedure. Pediatricians continue to play an important role in supporting the reproductive health care needs of their teen patients.

## Chapter 124

# ABDOMINAL DISTENTION

Peter F. Belamarich, MD

Abdominal distention can be a challenging clinical problem. There are no statistical definitions of distention available to pediatricians; therefore, determining what is likely to be pathological distention takes experience that includes many examinations of children of various ages in illness and in health.

Establishing the precise cause of abdominal distention in childhood from the history and physical examination alone can be also be difficult. The number of possible diagnoses is very large, and the most likely diagnoses vary greatly with the age of the child. Furthermore, not all distention is pathological. Healthy infants may have variable degrees of abdominal distention caused by aerophagia, and healthy toddlers may have a potbelly resulting from a combination of lumbar lordosis and relative hypotonia of the abdominal rectus muscles. The nonpathological distention often seen in infants and toddlers may exceed the mild distention seen with an intraabdominal malignancy. Therefore, a careful systematic approach should be used whenever concerns about abdominal distention are raised. The assessment of distention invites us to combine a systematic diagnostic thinking process and the art of physical diagnosis to minimize tests, radiation, discomfort, and expense.

## APPROACH TO THE CHILD WITH ABDOMINAL DISTENTION

### History

The history should establish the tempo of the obstruction, the presence or absence of gastrointestinal (GI) symptoms, pain, and constitutional symptoms.

Symptoms of GI obstruction (vomiting, pain, constipation, delayed passage of meconium at birth) or malabsorption (failure to thrive, diarrhea or greasy, bulky, malodorous stools) should be sought.

Although pain is present in most cases, an episode of acutely painful distention is a surgical emergency until proved otherwise. Painless distention raises the question of ascites, progressive organomegaly, tumors, and cysts, as well as abdominal hypotonia.

The presence of fever, weight loss, failure to thrive, anorexia, fatigue, irritability, or bone pain should be sought because these symptoms may suggest a malignancy; however, their absence does not exclude one.

See Table 124-1 for a list of symptoms that suggest specific causes of distention.

Medication use, including herbal and alternative therapies, should be reviewed, with particular attention to laxative dependence as a clue to Hirschsprung disease or another organic cause of constipation and to the use of agents that can cause GI ileus and constipation.

Travel history should be covered to explore the possibility of geographically specific causes of distention, such as ascariasis, which in many parts of the world is a common cause of GI obstruction.

Given the vast differential diagnosis, the past medical history should be comprehensive. Conditions that predispose children to an intraabdominal malignancy include the WAGR syndrome (Wilms tumor, aniridia, genitourinary abnormalities, and mental retardation) and Denys-Drash syndrome, which are associated with increased risk for Wilms tumor, and Beckwith-Wiedemann syndrome, which puts affected children at increased risk for Wilms tumor, hepatoblastoma, and adrenal carcinoma. Children with trisomies, DNA fragility syndromes, and immunodeficient states are at risk for lymphoma and leukemia. A history of abdominal surgery suggests the possibility of intestinal adhesions causing obstruction. Behavioral and psychiatric disorders should raise the question of a bezoar.

The family history should include questions about cystic fibrosis (meconium ileus), polycystic kidney disease, metabolic diseases, and whether any history exists of fetal demise or early neonatal death that might indicate an unrecognized metabolic disease, some of which produce hepatomegaly, splenomegaly, and congenital ascites.

In newborns, additional clues may be found in the pregnancy history: oligohydramnios suggests distal

**Table 124-1** Symptoms That Suggest Causes of Abdominal Distention

SYMPTOM	CAUSE
Fever	Peritonitis
Diffuse severe pain	Obstruction, peritonitis, pancreatitis
Constitutional symptoms—weight loss	Malignancy
Perception of a mass	Malignancy
Bilious or pernicious vomiting	GI obstruction, ruptured ectopic pregnancy
Progressive, asymptomatic distention	Malignancy, ascites
Malodorous stools	Malabsorption
Amenorrhea	Imperforate hymen
Weakness	Rickets

urinary obstruction, whereas polyhydramnios is seen with upper GI obstruction.

For infants and toddlers with otherwise asymptomatic distention, a diet history may suggest that the child is at risk for rickets. One must be careful to differentiate a parent's concern about the potbelly appearance of a toddler from more ominous reports of progressive or marked distention or the perception of a mass.

In female adolescents, the possibility of a pregnancy mandates that a confidential history of sexual activity be obtained. A history of amenorrhea despite advanced puberty raises the question of imperforate hymen with hematocolpos.

### Physical Examination

The value of an unhurried, calm, reassuring, and gentle approach to the anxious younger child with an abdominal problem cannot be overstated. Having the child's parents model the examination, using the child's doll or toy to demonstrate what will happen, is key to achieving this. To this end, sometimes the examination table must be forgone in favor of lying the child down across the parent's lap. The abdominal examination of an unwilling, anxious child who is struggling and crying is uniformly unsatisfying and nondiagnostic.

The profile of the abdomen should be inspected with the child in a supine position, noting whether the distention is generalized (maximum at the umbilicus) or localized. Box 124-1 presents commonly encountered causes for focal abdominal distention and common masses. The pattern and prominence of the

abdominal veins should be noted. Prominent superficial veins on the abdomen may indicate portal hypertension or obstruction to the systemic venous return. The abdomen should be auscultated for hyperactive bowel sounds (malabsorption, acute obstruction), rushes (incomplete obstruction), and absence of sounds (paralytic ileus), as well as for bruits (vascular malformation).

Percussion can be used to differentiate diffuse from the more focal epigastric tympani and to identify shifting dullness in older children.

Gentle palpation should begin from the lower quadrants and progress upward so that the inferior edge of the liver and spleen are appreciated (massive hepatomegaly may be missed if the liver is compressible and the liver's edge is near the child's pelvis). The abdomen should be assessed for focal or generalized tenderness. Involuntary guarding noted on gentle palpation is a sensitive sign of peritoneal inflammation; assessment of rebound tenderness in young children is vulnerable to false-positive results.

When an abdominal mass is appreciated, the examiner should note its location and whether it is painful, is mobile (intraabdominal) or nonmobile (retroperitoneal, malignant), moves with respiration (liver and spleen), is cystic or solid or malleable (fecal masses), is smooth or nodular, and whether it crosses the midline (often seen with neuroblastoma). Ballottement—"throwing" the kidney anteriorly with a finger in the costovertebral angle while palpating the surface of the abdomen with the other hand—can help elicit masses in the flank that cannot be appreciated with simple palpation.

#### BOX 124-1 Causes of Focal Abdominal Distention or Mass

##### EPIGASTRIUM

- Duodenal atresia
- Pyloric stenosis
- Malrotation
- Gastric duplication
- Bezoar

##### FLANK

- Wilms tumor
- Hydronephrosis
- Multicystic kidney
- Polycystic kidney
- Neuroblastoma
- Renal vein thrombosis
- Adrenal hemorrhage

##### RIGHT UPPER QUADRANT

- Choledochal cyst
- Hepatomegaly
- Hepatic tumors
- Hydrops of the gallbladder

##### LEFT UPPER QUADRANT

- Splenomegaly
- Splenic cyst

##### RIGHT LOWER QUADRANT

- Ovarian mass
- Intussusception
- Appendiceal abscess
- Crohn disease
- Fecal mass

##### LEFT LOWER QUADRANT

- Ovarian mass
- Fecal mass

##### HYPOGASTRIUM

- Hydrometrocolpos
- Hematocolpos
- Fecal mass
- Presacral teratoma
- Obstructed bladder
- Urachal cyst

Although rectal examination is often avoided, properly done it can add considerable information to the evaluation of children who have constipation, anal stenosis, Hirschsprung disease, and pelvic masses.

Infants who have ascites have bilateral bulging flanks in the supine position; in older children, the examiner may be able to elicit shifting dullness by percussion or appreciate a fluid wave. An acquired umbilical hernia may indicate massive ascites.

In female patients, a genital examination is necessary to exclude imperforate hymen with hydrometrocolpos or, in adolescents, hematocolpos and pregnancy. In both sexes, lower genitourinary tract malformation raises the question of upper genitourinary tract malformation.

Examination of the inguinal region and the scrotum in males for an inguinal hernia is always warranted with gaseous distention or symptoms of obstruction. Scrotal edema may accompany ascites caused by hypoalbuminemia.

Finally, an assessment of muscular tone and a search for the signs of rickets are warranted in all children whose distention remains unexplained.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis can be narrowed further based on whether the child has a tympanitic abdomen or prominent GI symptoms, a palpable mass, organomegaly, ascites, or hypotonia of the abdominal wall (Table 124-2). Causes of hepatomegaly and splenomegaly are reviewed separately in Chapters 162 and 196, respectively.

Life-threatening causes of abdominal distention are presented in Box 124-2.

## Tympanitic Abdomen in Newborns and Neonates

Tympanitic abdominal distention may occur in healthy infants, in infants who have systemic conditions, and in newborns who have congenital causes of intestinal obstruction.

Some healthy infants experience transient mild distention because of air swallowing with crying or feeding. This distention is variable, greatest after feeding or fussing, and absent at other times. Vomiting is

### BOX 124-2 Life-Threatening Causes of Abdominal Distention

- Sepsis
- Peritonitis (GI perforation, infected ascites, primary bacterial, chemical)
- Intraabdominal bleeding
- Liver, spleen, or GI laceration or hematoma
- Severe pancreatitis
- Splenic sequestration crisis
- Acute renal failure
- Acute liver failure
- Ruptured ectopic pregnancy
- Severe electrolyte disturbances or toxicological etiologies leading to ileus

**Table 124-2** Differential Diagnosis of Abdominal Distention Based on Physical Examination Findings

PHYSICAL SIGN	POSSIBLE CAUSES
Tympanitic abdomen	GI ileus GI obstruction Peritonitis Malabsorption Aerophagia Pneumoperitoneum
Palpable mass	Renal tumor or hydronephrosis Adrenal, sympathetic chain tumor Hepatomegaly or hepatic tumor GI duplication Mesenteric, omental cyst Ovarian cyst or tumor, hematocolpos Splenic or lymphatic enlargement or tumor
Ascites	Hypoalbuminemia from nephrosis, protein-losing enteropathy Hepatic cirrhosis, liver failure Heart failure Urinary ascites from a ruptured urinary tract Chylous ascites—congenital, traumatic, postoperative
Abdominal wall hypotonia	Generalized hypotonia Rickets Hypothyroidism
Signs of peritonitis	GI perforation Bacterial peritonitis Chemical peritonitis—leak of bile or pancreatic fluid

absent, and the stooling pattern and physical examination are normal.

In the ill newborn, many systemic conditions cause a paralytic intestinal ileus characterized by quiet, non-tender abdominal distention: sepsis, pneumonia, birth asphyxia, hypothyroidism, and electrolyte imbalance. In premature infants, necrotizing enterocolitis (NEC) should be considered.

Congenital causes of proximal GI obstruction causing distention in newborns include intestinal atresias, annular pancreas, and abnormalities of intestinal rotation and fixation. The most common proximal GI obstruction is duodenal atresia, characterized by polyhydramnios in 50% of patients and the onset of bilious vomiting in the first hours of life in conjunction with focal epigastric distention (Figure 124-1). Upright plain radiographs are diagnostic of duodenal obstruction when they demonstrate the double-bubble sign. Because malrotation is present in up to 19% of patients who have intrinsic duodenal obstruction, a barium enema should establish normal intestinal rotation in infants whose surgery is deferred.

Upper abdominal distention is a common, although not universal, finding in newborns and infants who have symptomatic intestinal malrotation, most of whom have bilious vomiting in the first 4 weeks of life. Plain radiographs may demonstrate a distended stomach or duodenal distention with a paucity of gas distally, or the radiographs may appear normal. Therefore, clinical suspicion even in the face of a normal plain radiograph warrants an upper GI series.

Congenital causes of lower intestinal obstruction include distal intestinal atresias, meconium ileus, Hirschsprung disease, small left colon syndrome, and anorectal malformations. Newborns who have lower intestinal obstruction typically develop generalized tympanitic distention over the course of 24 to 48 hours, with bilious vomiting and failure to pass meconium. Although an imperforate anus or an incarcerated hernia will be apparent on physical examination, differentiation of the remaining causes of lower intestinal obstruction involves radiographic evaluation.

Marked tympanitic abdominal distention can be a manifestation of pneumoperitoneum, which is demonstrated by upright and cross-table lateral abdominal radiographs revealing free air within the peritoneum. When pneumoperitoneum is associated with peritonitis, intestinal perforation is likely, and the causes

include NEC, volvulus, an intestinal obstruction causing perforation, appendicitis, and spontaneous perforations. In infants on a respirator, pneumoperitoneum may occur without peritonitis as a complication of pneumomediastinum.

### Tympanitic Abdomen Beyond the Neonatal Period

Beyond the neonatal period, the causes of a tympanitic abdomen include intestinal ileus, mechanical obstruction, pneumoperitoneum, and malabsorption.

Children with paralytic ileus have a clinical picture similar to that seen with distal mechanical bowel obstruction; however, bowel sounds are diminished or absent, and plain radiographs demonstrate air throughout the GI tract. Common precipitants include abdominal surgery, peritonitis, trauma, shock, sepsis, hypokalemia, and anesthesia, as well as numerous medications.

GI obstruction causing a tympanitic abdomen beyond the neonatal period can be either a late presentation of a congenital problem or an acquired condition, including an intraluminal obstruction such as pyloric stenosis, intussusception, a bezoar, meconium ileus equivalent, intestinal polyps, ascariasis, or an intrinsic tumor. Extraluminal obstructions include postoperative adhesions, an appendiceal abscess, a Meckel diverticulum, and extrinsic compression by abdominal or pelvic masses.

Tympanitic distention occurs in conjunction with the fat malabsorption syndromes, cystic fibrosis, and celiac disease. These conditions are characterized by steatorrhea and variable degrees of malnutrition and suboptimal growth. Although idiopathic constipation is extremely common throughout childhood and impaction can cause abdominal distention (Figure 124-2), marked distention or recurrent distention should not be attributed to functional constipation (see Chapter 134, Constipation).

### Abdominal Masses in Newborns and Neonates

Two-thirds of abdominal masses in neonates originate from the kidney or the urinary tract. Renal masses are

**Figure 124-1** Newborn infant with duodenal atresia and upper abdominal distention.

**Figure 124-2** Thirteen-year-old girl with severe fecal impaction.

retroperitoneal, nonmobile, and appreciated either in the flank or on deep abdominal palpation. Cystic masses predominate and have a slightly compressible quality. A multicystic kidney is the single most common neonatal flank mass. It can be appreciated on physical examination as a soft mass with a slightly irregular contour. The next most frequently encountered renal mass is caused by hydronephrosis. A smooth unilateral flank mass in an otherwise well newborn is usually from a ureteropelvic junction obstruction. Posterior urethral valves, a common cause of bilateral hydronephrosis and hydroureters in male infants, may present as bilateral flank masses or a palpable bladder. Newborns who have autosomal recessive polycystic kidney disease may have palpable bilateral firm flank masses, oliguria, hematuria, and hypertension. The most common renal tumor encountered in newborns is a mesoblastic nephroma, a tumor that can cause massive unilateral nephromegaly.

Renal vein thrombosis is a rare but important cause of a smooth flank mass and hematuria, which develop concurrently in an ill newborn after an episode of asphyxia, sepsis, or dehydration or in an infant whose mother has diabetes.

Of the remaining one third of neonatal abdominal masses that arise outside the urinary tract, neuroblastoma, GI duplications, hydrometrocolpos, and ovarian cysts account for a large proportion.

When a newborn has a palpable flank mass after a traumatic or breech delivery, the possibility of an adrenal hemorrhage should be considered, as should hepatic and splenic hematomas.

Female newborns may have a lower abdominal or pelvic mass from hydrometrocolpos. An imperforate hymen will be evident on the genital examination as a bulging round membrane within the introitus. A rectal examination can be diagnostic for the presence of a dilated vagina in higher obstructions.

Although rare, a significant number of benign epithelial cysts may arise in the neonatal period, including choledochal cysts (right upper quadrant), splenic cysts (left upper quadrant), mesenteric cysts (midabdominal, mobile in the transverse plane), and urachal cysts (hypogastrium). Retroperitoneal cysts include abdominal lymphangiomas and pancreatic cysts.

### Abdominal Masses Beyond the Neonatal Period

The differential diagnosis of masses in infants and older children includes late presentations of congenital masses, malignancies, fecal masses, bezoars, and pancreatic pseudocysts. Of the congenital masses, GI duplications, mesenteric cysts, and choledochal cysts may enlarge slowly and become apparent in later infancy or childhood. Similarly, an adolescent who has an imperforate hymen or vaginal septum may not become symptomatic with hematocolpos until the onset of cyclical uterine bleeding.

The abdomen is the site of origin of Wilms tumor, hepatic tumors, ovarian tumors, about 70% of neuroblastomas, and 30% of non-Hodgkin lymphomas. Neuroblastoma, Wilms tumor, and hepatoblastoma may produce an asymptomatic abdominal distention or mass that is noted by the parent during bathing or

dressing the child or by the physician on routine physical examination. Wilms tumor tends to occur in older infants and toddlers, with a peak incidence in 2- to 5-year-old children (Figure 124-3). Hepatoblastoma, the most common primary hepatic malignancy in childhood, is also overwhelmingly discovered as an asymptomatic abdominal mass, with a median age at diagnosis of 12 months. In the second decade, tumors detected as an abdominal mass are predominantly ovarian (Figure 124-4) or non-Hodgkin lymphoma.

Fecal masses are extremely common in childhood and adolescence and may be found in the right lower quadrant (when a redundant sigmoid colon loops to the right), in the hypogastrium, or in the left lower quadrant. They are mobile, nontender, and malleable. Reexamination after laxative therapy should confirm that the masses are no longer present.

Bezoars, which are intragastric concretions of indigestible material, can cause a large array of GI complications, including upper abdominal discomfort and a large mass. Most commonly, they result from the ingestion of hair.

### Ascites

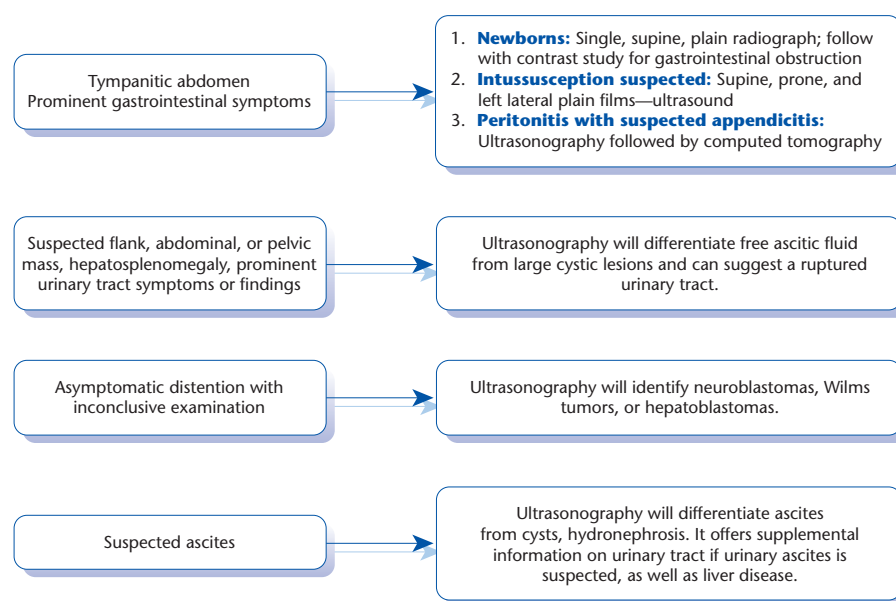

The newborn with ascites has a distended, nontympanic abdomen with bulging and dullness in the flanks, findings that may be mimicked by a massively dilated bladder, a severely hydronephrotic kidney, or a large ovarian cyst. In the newborn, ascites results most

**Figure 124-3** A, Abdominal distention from a right-sided Wilms tumor. B, Computed tomographic scan of tumor.

**Figure 124-4** Lower abdominal distention caused by ovarian teratoma.

**Figure 124-5** Initial radiographic approach to abdominal distention in infants and children.

often from a perforation within an obstructed urinary tract; in boys, posterior urethral valves are a common precipitant.

Beyond the neonatal period, ascites occurs most commonly as a consequence of nephrotic syndrome. It is also commonly seen in chronic liver disease with cirrhosis and portal hypertension, and in congestive heart failure.

Chylous ascites is a rare condition that occurs when lymphatic fluid leaks directly into the peritoneum because of a malformation or perforation of the intestinal lymphatics. The diagnosis is made by paracentesis.

### Abdominal Wall Hypotonia

Abdominal distention is frequently encountered in healthy infants and may also be seen in infants with a variety of neuromuscular conditions that produce generalized hypotonia. Hypothyroidism and rickets can cause abdominal distention to develop insidiously.

### Radiographic Approach

Although the history and physical examination sometimes provide the diagnosis, many children who have abdominal distention require radiographic imaging. The choice of initial imaging modality is dictated by clinical suspicion, primary findings on physical examination, and locally available resources and expertise.

Given that a single abdominal computed tomography (CT) scan can deliver the same radiation dose as 250 chest radiographs, the judicious and informed use of CT scanning for the evaluation of children with abdominal distention is encouraged.

Therefore, consulting with the radiologist is helpful. Some general guidelines for choosing an initial radiologic study are presented in Figure 124-5.

*The author wishes to thank Kenneth Kenigsberg, MD, for providing the photographs used in this chapter.*

### WHEN TO ADMIT

Abdominal distention in the presence of:

- Refractory vomiting, dehydration
- Peritonitis
- Toxic or septic appearance
- Moderate or severe pain that is undiagnosed or not well controlled
- Mass suspicious for malignancy
- Urgently needed surgical or radiologic procedures

## Chapter 125 ABDOMINAL PAIN

Anthony M. Loizides, MD; Katherine Atienza Orellana, DO;  
John F. Thompson, MD

Abdominal pain is one of the most common symptoms in children and adolescents and is estimated to account for approximately 5% of unscheduled office visits. Acute abdominal pain may require medical or surgical intervention to prevent disability or even death. The precise number of children who experience acute abdominal pain is unknown, but acute appendicitis is the most common abdominal emergency in the pediatric population, with an estimated 81,000 appendectomies performed in the United States annually. More commonly, abdominal pain is a recurrent symptom not associated with physical disability or mortality.

Abdominal pain is determined by several different factors, including the provocation itself, the type of receptor involved, the organization of the neural pathways from the site of injury to the central nervous system, and complex communication between transmission, understanding, and reaction to pain. Abdominal pain is transmitted through distinct types of afferent nerve fibers. These result in the perception of 3 different types of abdominal pain: visceral, parietal, and referred pain.

The principal mechanical signal to which visceral nociceptors are sensitive is stretch, and visceral pain is transmitted by nonmyelinated nerves that are found in muscle, mesentery, peritoneum, and viscera. Pain from abdominal viscera tends to be burning, dull, diffuse, crampy, poorly localized, more gradual in onset, and long in duration. Abdominal organs convey sensation to both sides of the spinal cord; therefore, visceral pain is usually perceived to be in the midline. The area involved may be contingent on the organ affected.

For example, lower esophageal, gastric, and duodenal pain tends to be felt in the epigastrium. Small intestinal distention may be periumbilical or in the hypogastrium. Colonic pain may be felt in the lower abdomen. Innervation of most viscera is multisegmental, and because there are fewer nerve endings in the viscera than in more sensitive organs such as the skin, visceral pain is not well localized. Secondary effects such as sweating, restlessness, nausea, vomiting, perspiration, and pallor often accompany visceral pain. The patient may shift position in an attempt to relieve the distress.

Parietal pain is mediated by myelinated nerve receptors that are distributed principally to skin and muscle. These pain receptors respond to tearing or inflammation. Pain is perceived as sharp, sudden, and well-localized such as that which follows an acute injury. Parietal pain occurring from injurious stimulation of the parietal peritoneum is more powerful and more precisely localized than visceral pain. In acute appendicitis, early vague periumbilical visceral pain is followed by the localized parietal pain at McBurney point that is produced by inflammatory involvement of the parietal peritoneum. Parietal pain is typically heightened by movement. Reflexive responses, such as abdominal rigidity and involuntary guarding, are facilitated by spinal reflex arcs that contain parietal pain pathways.

Referred pain results from the interplay between visceral and parietal pain. It is felt in regions distant from the diseased organ and results when visceral and somatic neurons from different areas meet at second-order neurons in the same spinal segment as nerve fibers from cutaneous dermatomes. Examples of this type of pain include referred right scapular pain secondary to acute cholecystitis and mid-back pain from acute pancreatitis.

Functional abdominal pain (FAP), the most common cause of chronic abdominal pain in the pediatric population, was first characterized by Apley and Naish as pain that occurs at least 3 times over a period of 3 or more months severely enough to affect daily activities in children older than 3 years. The prevalence of FAP is estimated to be between 0.3% and 19%, although in large studies the prevalence is far lower, 0.3% to 8%. One reason for the broad range may be the lack of uniformity of criteria for making the diagnosis of FAP: its definitions may be too broad and may include other functional gastrointestinal disorders, such as functional dyspepsia.

A multidimensional measurement of FAP has been created, which, according to the Rome III criteria, must include episodic or continuous abdominal pain, insufficient criteria for other functional gastrointestinal disorders, and absence of an inflammatory, anatomic, metabolic, or neoplastic process that explains the subject's symptoms. The experience of the pain must occur once a week for at least 2 months. Regardless, no consensus exists on an exact definition. Some trends have been noted, such as a higher prevalence of FAP in girls. The highest prevalence occurs in children between 4 and 6 years of age and in early adolescence. Studies have also demonstrated associations between FAP and the child's family dynamics (eg, children

living in a single-parent household are more likely to experience chronic abdominal pain), psychological comorbidity such as anxiety, and socioeconomic environment (eg, children living in low-income, low-educated-worker families are more likely to experience pain).

Criteria have been established to categorize FAP. Initially, the Rome I criteria, later updated as Rome II, improved the definition of functional gastrointestinal disorders. Although this classification system can help categorize patients so that appropriate treatment options can be considered, not all children can be clearly placed in these categories. Some authorities have argued against using the classification in children, with one major reason being that the most common location of FAP is periumbilical pain, which is not in the Rome II criteria. Twenty-seven percent of children with abdominal pain do not meet Rome II criteria overall.

Pediatric gastroenterologists have identified and developed similar criteria for childhood functional disorders, including FAP. These criteria—the Rome III Criteria for Functional Bowel Disorders Associated With Abdominal Pain or Discomfort in Children—are based on symptom classification. Four classes were identified, including functional dyspepsia, irritable bowel syndrome, childhood functional abdominal pain as defined above (with a subgroup of children having childhood functional abdominal pain syndrome), and abdominal migraine. The usefulness of the Rome III criteria still needs to be established.

As difficult as characterizing different types of FAP is assessing the effectiveness of various treatments. Significant inconsistencies exist in the methodologic approaches currently used to assess pain. The influence of age and developmental maturation, individual differences (eg, temperament, coping patterns), family interactions, and community and cultural contexts may influence the expression of FAP, and these areas have not been addressed in the assessment of pain. To attend to some of these issues, a multidimensional analytic approach has been developed to assess the primary outcome in clinical trials.

In light of suboptimal classification and assessment tools, a symptom-based differential diagnosis with an emphasis on identifying the warning signals for organic disease is currently the most useful approach to patient care. Pediatricians and other physicians must recognize that chronic abdominal pain can lead to significant dysfunction and disability, with school absences, repeated visits to health care professionals, and secondary psychological problems if assessment and initiation of treatment are either ignored or delayed.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of acute abdominal pain can be subdivided into 3 broad categories: conditions that require immediate surgical intervention (Box 125-1), conditions that may be managed medically at first but may require surgical involvement (Box 125-2), and conditions that can be managed medically (Box 125-3). The differential diagnosis of acute abdominal pain based on age is provided in Box 125-4. The differential diagnosis of chronic or recurrent abdominal pain include those functional entities defined in the Rome III criteria as well as nonfunctional entities as shown in Box 125-5.

### BOX 125-1 Differential Diagnosis of Acute Surgical Abdomen

- Closed loop intestinal obstruction
- Volvulus (gastric, midgut, sigmoid)
- Incarcerated hernia (inguinal, internal, external)
- High-grade bowel obstruction
- Nonreducible intussusception
- Malrotation with Ladd bands
- Ovarian torsion
- Testicular torsion
- Acute appendicitis
- Perforated viscus with diffuse peritonitis or toxicity
- Ruptured tumor
- Ectopic pregnancy

### BOX 125-2 Differential Diagnosis of Acute Abdominal Pain That May Require a Combined Surgical and Medical Approach

- Partial small bowel obstruction
- Postsurgical adhesions
- Crohn disease
- Lymphoma
- Periappendiceal abscess
- Abdominal abscess
- Cholecystitis
- Gallbladder hydrops
- Pancreatitis
- Pancreatic pseudocyst
- Toxic megacolon or typhlitis

Entities that may require combined surgical and medical management are primarily associated with the gastrointestinal lumen as well as its associated organs (see Box 125-2) and can include postsurgical complications such as abdominal abscess or pancreatitis.

The concept of *referred pain* is especially relevant when discussing acute abdominal pain in children. A complete history may provide crucial information that suggests the abdominal pain may originate outside the abdomen. For example, a 3-year-old who has pneumonia may have inflammatory irritation of the diaphragm, resulting in acute abdominal pain as the presenting complaint. In addition, perihepatitis (Fitz-Hugh-Curtis syndrome) can produce acute abdominal pain, and the physician should be sensitive to an adolescent girl's possible reluctance to spontaneously disclose a history of sexual intercourse. The differential diagnoses of medical entities, including those that are extraabdominal or systemic, are listed in Box 125-3.

### BOX 125-3 Differential Diagnosis of Acute Abdominal Pain That May Require Medical Management

|---|--|

Box 125-4 lists some of the major diagnostic considerations for acute abdominal pain in children by age. Although diagnostic considerations overlap for each age group, the child's age and physiologic development can help the physician focus the differential diagnosis. For example, Hirschsprung disease should be considered more likely in an infant in the first weeks of life; Mittelschmerz should most certainly be in the differential diagnosis for an adolescent girl.

The cause of chronic abdominal pain in an adolescent female merits particular attention as it may be gynecologic, resulting from dysmenorrhea, endometriosis, pelvic inflammatory disease, or ovarian abnormalities.

Dysmenorrhea is common among adolescent females: up to 90% report symptoms when surveyed, but only 40% have told their physician about the pain. Dysmenorrhea is categorized into primary and secondary dysmenorrhea, depending on whether there is underlying pelvic pathology. Symptoms usually begin 6 to 12 months after menarche. Patients complain of lower abdominal pain that is crampy, spasmodic, stabbing, or dull. The pain typically occurs during menstruation but can begin a day or 2 before the onset of menses. Other symptoms can include nausea, vomiting, and diarrhea (see Chapter 141, Dysmenorrhea). Adolescents with endometriosis can present with cyclic abdominal pain,

- Vasculitis (especially Henoch-Schönlein purpura)
- Angioneurotic edema
- Acute intermittent porphyria

nausea, diarrhea, and constipation in addition to typical symptoms of dysmenorrhea. The pain may be severe enough for patients to miss school, visit their pediatrician, or go to an emergency department for medical care. Sexually active adolescents can have lower abdominal pain from pelvic inflammatory disease and may even have fever and vomiting depending on the severity of the infection. Ovarian abnormalities that may cause pain include ovarian cysts, ruptured ovarian cysts, ovarian torsion, and Mittelschmerz.

Constipation is a frequent cause of abdominal pain and should be considered when a child presents with chronic abdominal pain. Three percent of general pediatric outpatient visits and 25% of pediatric gastroenterology consultations are related to possible dysfunction of defecation. The stool history may be unreliable, and an abdominal radiograph may not be helpful, but serious consideration should be given to empirical treatment with a stool softener (see Chapter 134, Constipation).

**EVALUATION****History**

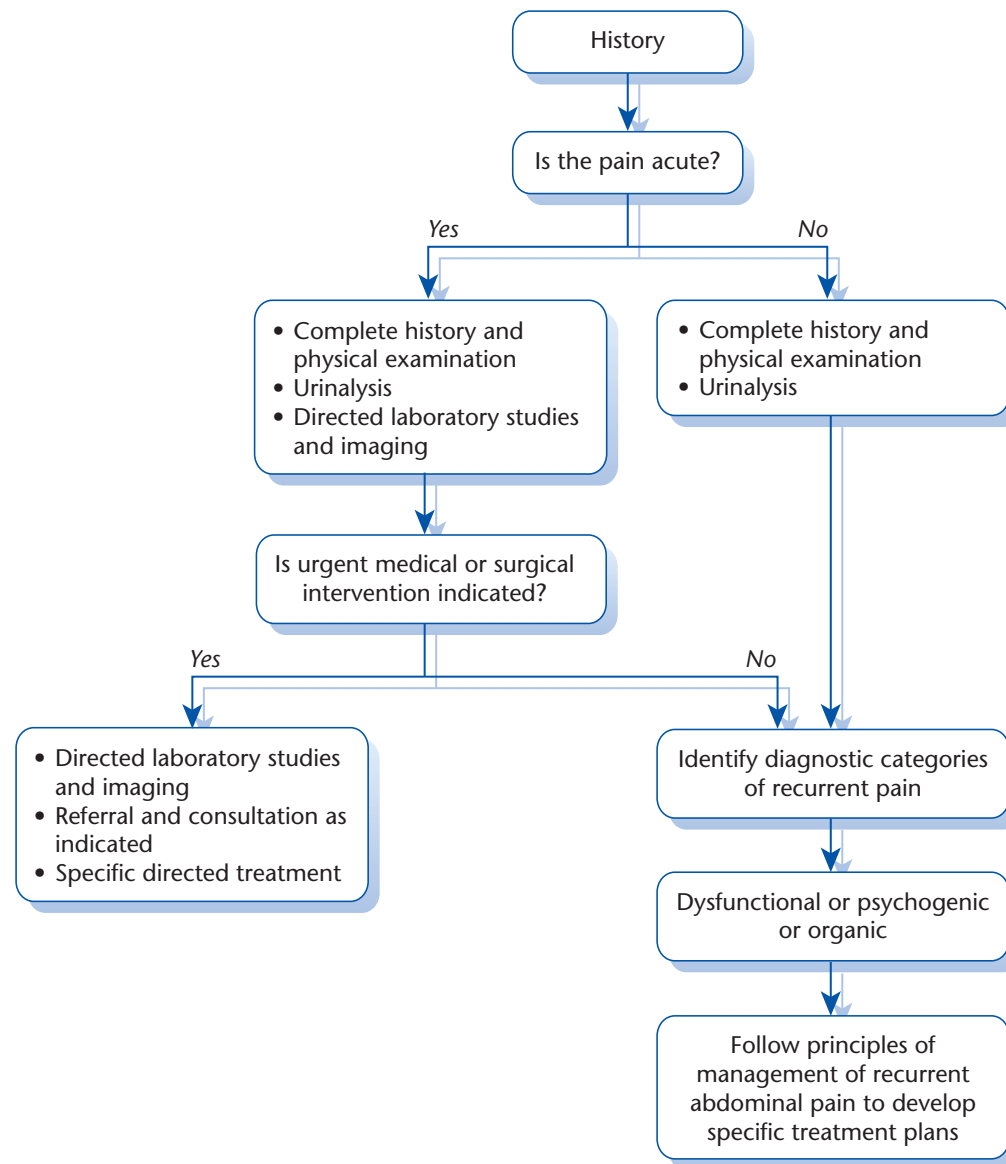

The approach to the evaluation of abdominal pain begins with a complete history and a thorough physical examination. The findings should direct the use of selected laboratory studies that are based on a reasonable differential diagnosis and will permit a clear therapeutic strategy to be created. Figure 125-1 summarizes the evaluation of the child or adolescent who has abdominal pain. The history alone accounts for most of the data the physician uses in making a diagnosis.

A systematic history should elicit information about the location, onset, and severity of the pain, alleviating

and precipitating factors, and associated symptoms. The timing of the onset and changes in the intensity, location, and quality of pain over time are essential factors in determining its cause. For children or adolescents who have recurring abdominal pain, information about the timing of the onset of the pain in relation to other events (eg, mealtime, school days), as well as the duration of each episode and the frequency of recurrence, is helpful. The effect of abdominal pain on school, work, sleep, and mood should be assessed. Additional information about family (inherited disorders, concurrent illnesses, chronic pain disorders), medical history (prior surgery, chronic medication, faltering growth), and environmental or behavioral factors (recent changes in family or school, travel, unusual food) should also be obtained. In adolescents, additional history should include menstrual history in females, sexual history, drug and alcohol use, and screening for depression. The timing of abdominal pain in relation to menses must be considered.

One must keep in mind that pain frequency, severity, location, presence or absence of associated symptoms, and effects on lifestyle cannot be used to distinguish between an organic or a functional cause for chronic abdominal pain. Nonetheless, children with FAP are more likely than children without FAP to have headache, joint pain, anorexia, vomiting, nausea, excessive gas, and altered bowel symptoms. The presence of alarming symptoms or signs suggests a higher probability or prevalence of organic disease and may justify performing diagnostic tests and referring the child to a subspecialist. Alarm symptoms or signs include, but are not limited to, involuntary weight loss, deceleration of linear growth, gastrointestinal blood loss, significant vomiting, chronic severe diarrhea, persistent right upper or right lower quadrant pain,

**Figure 125-1** Evaluation of child or adolescent who has abdominal pain.

unexplained fever, and family history of inflammatory bowel disease (see When to Refer). No single test can diagnose FAP. In patients with FAP a component of pain can be visceral hyperanalgesia, which provides a physiologic explanation of symptoms in children who have distinct functional gastrointestinal disorders.

The physician should help the family understand the importance of the history during the assessment. Both the parents and the patient should be interviewed. Patients must feel comfortable in discussing their own symptoms and concerns, even if these are different from those expressed by the parents. Confidentiality should be addressed with the adolescent patient when the parent is not present. Obtaining a history from the patient without the parents is therefore often useful; similarly, the parents may want to relate some of their concerns without the child being

present. Important diagnostic information can be missed if the pediatrician does not give the child and parents the opportunity to provide separate histories.

In addition to the presence of specific symptoms and positive history, negative aspects of the history can provide important information to narrow the differential diagnosis. For example, the absence of dysuria in an older child or adolescent would make the diagnosis of urinary tract infection unlikely.

### Physical Examination

Specific findings on the physical examination of children with FAP have rarely been described. The presence of tenderness on abdominal palpation has been reported to be characteristic of children with recurrent episodes of abdominal pain without evidence of organic disease, but most children's physical

examination will be normal. A normal examination and the absence of alarm signals point toward a functional diagnosis for abdominal pain. A complete physical examination, however, including a careful external examination of the urethral orifice and vaginal orifice as well as a rectal examination, should always be part of an initial assessment of abdominal pain. The history of the presenting symptoms will alert the pediatrician to consider more specific aspects of the physical examination.

### Laboratory Evaluation

Laboratory and diagnostic studies performed without any medical indications are generally not helpful and may actually hinder the therapeutic suggestions made by the pediatrician in FAP. The common pitfall of over-testing occurs when the physician responds to the parents' initial request to rule everything out by performing a battery of laboratory or radiographic studies. Maintaining a systematic approach to FAP will not only minimize the use of expensive, unnecessary laboratory studies but will also decrease recurrent emergency visits and, most important, prevent a delay in beginning effective treatment.

Dysfunctional and psychogenic causes account for most diagnoses of FAP, with organic causes identified in only approximately 5% to 8% of cases. However, diagnostic testing is indicated when alarm signals or abnormal physical findings suggest the possibility of an organic disorder. Tests to consider are listed in Box 125-6. When the history and physical examination indicate a dysfunctional or psychogenic cause, urinalysis could suffice as the initial laboratory study, but suggested screening laboratory tests are listed in the table below.

Laboratory and other diagnostic studies such as urinalysis (particularly in female patients of childbearing age), stool, or genital tract cultures; serum chemistries or erythrocyte sedimentation rate; radiographic studies (eg, barium swallow, upper or lower

gastrointestinal series, gallbladder series); and abdominal or pelvic ultrasound or computed tomographic scans should be directed to evaluate specific concerns identified in the history and physical examination. For example, when pancreatitis is suspected, laboratory investigations should include amylase and lipase. When indicated, abdominal and pelvic ultrasound provides a safe, noninvasive way to assess bowel and pelvic organ structures and help clarify the need for urgent surgical intervention (eg, intussusception, ovarian torsion, kidney abscess). In general, the physician should consider the least invasive procedures first, keeping in mind the cost of special studies in terms of pain, discomfort, and time.

Common laboratory tests (complete blood cell count, erythrocyte sedimentation rate, comprehensive metabolic panel, urinalysis, stool parasite analysis) are not helpful in distinguishing between organic and functional abdominal pain. The coexistence of abdominal pain and an abnormal test result does not necessarily indicate a cause-and-effect relationship. For example, eliminating dietary lactose as the treatment for patients with demonstrable lactose malabsorption does not necessarily result in the resolution of abdominal pain. Children found to have *Helicobacter pylori* infection are not more likely to have abdominal pain than children without *H pylori*.

### Imaging Studies

Ultrasound of the abdomen or pelvis is not useful in the absence of alarm symptoms. When atypical symptoms are present, such as jaundice, urinary symptoms, back or flank pain, vomiting, or abnormal findings at physical examination, abdominal and pelvic ultrasound is more likely than not to detect an abnormality. Endoscopy with biopsy in the absence of alarm symptoms similarly fails to reveal organic disease. Insufficient evidence exists to suggest that the use of esophageal pH monitoring in the absence of alarm symptoms results in finding organic disease. In patients who experience recurrent vomiting, an upper gastrointestinal series should be considered to define potential anatomic abnormalities such as gastric outlet disorder or malrotation. The choice of radiologic test should be guided by the differential diagnosis generated by the history and the physical examination.

### TREATMENT

The treatment of abdominal pain that results from an organic process should be pursued according to accepted practice guidelines for that condition. The treatment of FAP should be approached as a biopsychosocial phenomenon. FAP is still real pain. However, the response to pain can be subjective and understood through life experience. The treatment may therefore be a combination of psychotherapy, pharmacology, dietary, or alternative medicine techniques. It must always begin with educating the child and parent about the cause of the pain and the treatment plan. This approach not only improves the adherence to the treatment plan but also has been shown to affect the outcome. Treatment response may be influenced by whether the parents perceive the pain to have an organic cause. Similarly, children of parents

#### BOX 125-6 Suggested Screening Laboratory Tests

##### ALL PATIENTS

- Complete blood count with differential
- Erythrocyte sedimentation rate
- Comprehensive metabolic panel
- Stool hemocult

##### DIARRHEA

- Stool ova and parasite
- *Giardia* enzyme-linked immunosorbent assay
- *Clostridium difficile* toxin or PCR
- Celiac panel
- Lactose or fructose breath test
- Dyspepsia
- *Helicobacter pylori* stool antigen testin

who are open to a psychiatric consultation are more likely than not to report less pain.

## MANAGEMENT

A discussion of FAP as a real entity that is a product of an alteration in the brain-gut axis makes understanding the cause of the pain easier for parents. A good analogy is that of a migraine: no specific test exists to confirm the diagnosis, but stress and other inciting events may trigger a headache. When explained this way, parents may be better able to understand that the current thinking of autonomic dysfunction and visceral hypersensitivity as causes of the child's recurrent FAP does not mean that the pain is purely in the child's head or solely the effect of an undiagnosed physical ailment. Equally important is to inform the parents that the goal of therapy is not so much to arrive at a diagnosis, but rather to be able to have the child resume the lifestyle that preceded the onset of the abdominal pain, including school attendance, sleep patterns, and appetite.

## Psychosocial Treatment

Several different psychological strategies have been tried in a variety of conditions associated with functional pain, including treatment aimed at individuals or parent-child couples in one-to-one contacts with a therapist, group-based interventions, or a mixture of individual and group treatment. Psychological treatments, principally relaxation and cognitive-behavioral therapy, are effective in reducing the severity and frequency of chronic headache in children and adolescents. However, no evidence has been found for the effectiveness of psychological therapies in attenuating pain in conditions other than headache.

Cognitive-behavioral therapy that combines operant elements and stress management may provide an effective treatment for FAP, however. Cognitive-behavioral therapy results in short-term improvement, with more than one-half of patients experiencing freedom from pain. The child's coping skills and the parent's caregiving strategies predict the effectiveness of treatment. Disengagement and involuntary engagement are correlated with increased anxiety, depression, and somatic symptoms. Anxiety as a comorbidity has also been associated with FAP, and therefore psychological therapy may be used as a strategy in treating FAP.

Alternative medical techniques for the treatment of functional gastrointestinal disorders, including FAP of childhood, are becoming more common. Specific mind-body techniques include various breathing techniques, guided imagery, progressive muscle relaxation, biofeedback, hypnosis, cognitive-behavioral training, and music therapy. Of those techniques, guided imagery, relaxation, biofeedback, and hypnosis have shown the most promise in treating FAP of childhood. Reported improvement in the pain, fewer school absences, better engagement in social activities, and fewer visits to the physician's office may result from guided imagery and progressive relaxation techniques taught over approximately 4 office visits. Such techniques are easy to learn and teach and are office friendly, even with children.

## Medication

Many drugs have been used in the attempt to treat FAP in childhood, including famotidine, pizotifen, and peppermint oil. Peppermint oil in the form of a pH-dependent, enteric-coated capsule has been shown in evidence-based studies to be helpful in alleviating abdominal pain. Other commonly used medications are anticholinergics, antiemetics, antidepressants, and simethicone, but they have not yet been adequately studied. Citalopram, a selective serotonin reuptake inhibitor, has been used to treat FAP, with improvement of abdominal pain, anxiety, depression, and functional impairment. Amitriptyline has also been shown to reduce pain, depressive symptoms, and somatization in children with FAP and irritable bowel syndrome.

Probiotics have been used to treat alterations in gut flora in ulcerative colitis and antibiotic-associated diarrhea, but there is little evidence to support their use in FAP. Only one study has shown that the probiotic VSL#3 improves abdominal pain as well as bloating, gassiness, discomfort, and quality of life in patients with irritable bowel symptoms. Other studies suggest that *Lactobacillus GG* does not relieve abdominal pain but can decrease its frequency and reduce bloating.

## Dietary Interventions

Dietary manipulation has been used to treat the pain in functional disorders. Common dietary interventions include a high-fiber diet, avoidance of lactose, an oligoantigenic diet, and a low-oxalate diet in abdominal migraine. A high-fiber diet may be helpful primarily in constipated children, to substitute for nutrient-poor, high-fat, and high-calorie diets. Avoidance of high-fructose corn syrup and glucose-based drinks and of sugar-free gum and candy may improve symptoms. Sorbitol, the sugar substitute in gum and candy, can cause bloating, cramping, abdominal pain, and diarrhea. Dietary manipulation is easily understood by parents and children and can empower the family.

## CONCLUSION

The causes of abdominal pain range from acute, life-threatening disease to chronic, functional conditions. Regardless of the cause, the consequences of abdominal pain can be far reaching and can affect not only the emotional and psychological well-being of the child but also the social and economic dynamics of the family. The need to diagnose and treat emergent conditions quickly must be balanced with unnecessary testing when a functional cause seems likely. In the case of functional conditions, a caring approach that educates and reassures the patient and parents is essential for good adherence and an effective therapeutic relationship.

## WHEN TO REFER

- Involuntary weight loss
- Deceleration of linear growth
- Gastrointestinal blood loss

- Significant vomiting
- Chronic severe diarrhea
- Persistent right upper or right lower quadrant pain
- Unexplained fever
- Family history of inflammatory bowel disease
- Extraintestinal symptoms
- History of psychiatric disorder
- Abnormal test results
- Anemia or low mean corpuscular volume
- Peripheral eosinophilia
- Increased erythrocyte sedimentation rate
- Increased transaminases
- Increased blood urea nitrogen or creatinine
- Hypoalbuminemia
- Low complement-4 protein

### WHEN TO ADMIT

Hospitalization is seldom indicated for patients with FAP; in fact, some studies suggest that placing patients with FAP in the hospital may lead to worse outcome. Some patients do experience relief of symptoms during hospitalization. However, no data suggest that the natural history of the pain is affected. Hospitalization does not help the fundamental goals of environmental modification and will likely reinforce pain behavior. Hospitalization is required in the following circumstances:

- Surgical or medical emergency as determined by diagnostic or therapeutic intervention
- Inability to tolerate enteral nutrition
- Inability to maintain hydration
- Diagnosis that requires observation to evaluate the progress or natural history of the illness

### Chapter 126

## ALOPECIA AND HAIR SHAFT ANOMALIES

Nancy K. Barnett, MD

Hair matters. It does not serve an essential function, inasmuch as people can live without it. Nevertheless, the symbolism over the ages, from Samson to John Lennon, and the emotional investment people have in their hair make any of its abnormalities a matter of concern. This anxiety is particularly so with alopecia: loss of hair is a disturbing event.

### INTRODUCTION

A sequence of events makes up the life of a single hair, from active growth over 2 to 6 years, a busy period known as the *anagen phase*, to passivity, a resting period of about 3 months, known as the *telogen phase*. As many as 15% of scalp hairs may be in the telogen phase at any specific time. These hairs are soon lost in the constant turnover of scalp hair, a continuous shedding that is hardly apparent to a casual observer. Surprisingly, about 50% of the hair must be shed for loss to be noticeable. Normally, up to 100 hairs are lost from the scalp daily, and 200 are lost with shampooing.

Hair loss may increase to as much as 60% during a period known as a *telogen effluvium*. During such a period, the situation is similar to that of animals, which shed seasonally. In humans, this change in the normal anagen-to-telogen ratio may occur after a period of stress, such as a prolonged fever, a pregnancy, or a severe illness. It may occur in either gender and results in a diffuse, nonpatterned and nonscarring loss of hair. The diagnosis of telogen effluvium can be confirmed simply by plucking a group of hairs and examining them microscopically (see Evaluation, later in this chapter). Notably, plucking these hairs does not hurt because they are in the resting phase, with the number of resting hairs increased well beyond the usual 10% to 15%.

Excessive hair loss is a matter deserving careful attention. A precise, pointed history and physical examination are necessary. Determining whether an alopecia is scarring or nonscarring is important. The pediatrician must not limit the examination

simply to the site of hair loss. The whole body and all its hair-bearing parts must be observed and hairs themselves examined microscopically. Under the light microscope, the normality of the individual hair and the ratio of anagen to telogen hairs can be judged. The pediatrician may need to consult with a dermatologist.

Lanugo, the first hair made by hair follicles in utero, feels silky and covers the entire body of the fetus. It is most often shed in utero, to be replaced by hair that begins to grow on the scalp in the third trimester; continues to grow after birth, and is lost a few months after birth in a normal process that results in temporary near-baldness. In many instances, parents are concerned with the thinning or with a more markedly localized area of loss, usually over the occiput, once thought to be the result of the pressure of the head as the infant lies in the crib. Finally, however, the lost early hair is gradually replaced by new hair, which has more of a “feel” to it; thicker, usually darker, and more stable, it grows longer before loss and does not shed quite so readily.

The constant ebb and flow of growth and shedding and the extreme activity of the hair follicle put it at great risk when exposed to antimetabolites and mitotic inhibitors. When a child loses scalp hair rather suddenly, the physician should be concerned with the possibility of a toxic event. Children treated with antimetabolites for a malignancy suffer hair loss because of the damage done by the drugs during the anagen phase, resulting in an anagen effluvium. Occasionally, similar hair loss is caused by accidental poisoning, as with rat poison that contains thallium or coumarin. In most instances, over a period of several months, new hairs will replace lost hairs, unless the exposure to the toxic element is chronic.

The prognosis for the return of hair depends in large part on elimination of the toxic stimulus and on whether the loss is accompanied by scarring. Loss with scarring (eg, from iatrogenic scalp injury during delivery or from a burn) is permanent. Additionally, hair will not grow at the site of most nevi and hemangiomas. In children, alopecia of both known and unknown causes usually occurs without scarring, as in alopecia areata (spotty loss of scalp hair); alopecia totalis (loss of all scalp hair); alopecia universalis (loss of all scalp and body hair); drug-induced, postfebrile, and postpartum alopecias; and alopecias associated with an endocrinopathy (hypothyroidism, hyperthyroidism, or hypoparathyroidism) or a nutritional deficiency (vitamins A, B, and C, or kwashiorkor).

When scarring is present, as with a kerion associated with tinea capitis, keloid formation, or discoid lupus erythematosus, little hope exists for hair recovery.

## EVALUATION

Appropriate diagnosis requires microscopic differentiation of the hair and its root in both the anagen and the telogen stages. Anagen hairs have fat, healthy follicle bulbs and an attached emerging long terminal hair, whereas telogen hairs have a small bulb and an attached hair resulting in a club-shaped appearance. Deformities of the hair shaft can be seen, particularly

with aminoacidopathies and in a variety of rare syndromes, including Menkes kinky hair syndrome. The physician can differentiate microscopically monilethrix (usually an inherited, autosomal dominant disorder in which the diameter of the hair shaft varies) from pili torti (a disorder in which the hair is twisted on its long axis).

## DIFFERENTIAL DIAGNOSIS

A variety of congenital and hereditary disorders can produce hair loss, either total or less obvious with thinning (Table 126-1). True congenital alopecia is rare and may be inherited as an isolated autosomal recessive trait or as one feature of a significant hereditary disorder. Hairs may be thin or poorly anchored to the scalp or have a variety of shaft abnormalities. The pediatrician must look for signs of ectodermal dysplasia, and thus consider radiographic exploration for skeletal defects (as with cartilage-hair hypoplasia, congenital ectodermal dysplasia, or orofaciocigital syndrome), as well as for evidence of inherited metabolic or endocrine disorders such as phenylketonuria, homocystinuria, and congenital hypothyroidism. Children with serious chromosomal defects (eg, de Lange syndrome or trisomy 13 syndrome) usually provide a surfeit of signs and symptoms beyond simple loss of hair.

## Hair Shaft Anomalies

Anomalies of the hair usually result in a stubbly growth of broken hair rather than true alopecia. Ectodermal defects, brittle fingernails, or perhaps cataracts and tooth anomalies may accompany hair shaft anomalies. Fragile hair with resultant breakage (trichorrhexis) and stubble can be seen in a variety of rare conditions. Trichorrhexis nodosa is a familial condition in which the hair is fragile without other associated findings. Children with argininosuccinic aciduria, a rare inborn error of metabolism, have stubbly hair and show evidence of severe intellectual disability in the first year of life.

The texture of hair may be helpful in finding the source of difficulty. In an infant who has hypothyroidism, the hair may be coarse, brittle, and without luster; with progeria and cartilage-hair hypoplasia syndrome, it may be fine and even silky. In all these circumstances, the hair may break off, and apparent baldness increases. Whenever the hair is abnormal, it becomes weakened, fragile, and fractured, and it may be lost or unevenly shortened, often resulting in a stubbly, ragged alopecia. Given that a variety of abnormalities (congenital, traumatic, or endocrine) can lead to such fragility and loss, referral to a dermatologist is appropriate so that a specific diagnosis can be pursued.

## Loose Anagen Syndrome

Loose anagen syndrome is characterized by hairs that are quite easily and painlessly pulled from the scalp. Generally, but not always, affected children are blond female preschoolers between 2 and 5 years of age. Their hair appears sparse. The individual hairs are not fragile. On examination, they have misshapen anagen bulbs with a cuffed cuticle and no external root sheath.

**Table 126-1 Distinguishing Characteristics of Alopecia**

CONDITION	PATTERN OF LOSS	PULLED-HAIR CHARACTERISTICS AS EXHIBITED WITH LIGHT MICROSCOPY
<b>NONSCARRING WITH HAIR SHAFT ABNORMALITIES</b>		
Trichorrhexis nodosa	Fragile, short hair with grayish-white nodules	Nodes along hair shaft similar to interlocking broom or brush ends
Monilethrix	Fragile, short, stubble-like growth	Variable shaft thickness gives beaded appearance with internodal breakage
Pili torti	Fragile, short, light-colored hair appears spangled as a result of light reflection	Irregularly spaced twists along the shaft appear flattened
<b>NONSCARRING WITHOUT HAIR SHAFT ABNORMALITIES</b>		
Alopecia areata	Sharply demarcated, round, nearly bald patches appearing suddenly	Exclamation-point hairs from periphery of patches with poorly pigmented shaft and tapered attenuated bulb
Androgenetic alopecia	Thinned scalp hair in common male baldness pattern or diffuse thinning with retained frontal hair in the female	Increased telogen-to-anagen ratio Biopsy shows miniaturized anagen bulbs
Trichotillomania	Irregularly shaped areas of thinned stubble of varying lengths	Normal cuticle, shaft, and anagen bulb of varying lengths
Traumatic alopecia	Bizarre patterns conforming to site and method of injury (eg, head trauma, braiding)	Normal cuticle, shaft, and anagen bulb of varied lengths
Telogen effluvium	Diffuse thinning with easy epilation from all areas of scalp	More than 25% of pulled hairs are telogen club hairs with no pigment
Anagen effluvium	Significant thinning	Tapered anagen bulbs
Loose anagen syndrome	Slight diffuse or patchy thinning	Anagen hairs have misshapen pigmented bulbs with ruffled cuticle
<b>POTENTIALLY SCARRING WITHOUT HAIR SHAFT ABNORMALITIES</b>		
Tinea capitis and kerion	Varied, ranging from round, minimally inflamed alopecic area with slight seborrheic scale to the boggy, tender, often pustular, severely inflamed kerion	Potassium hydroxide preparation of broken hairs (black-dot hairs) reveals clusters of chains of arthrospores around or in hair shaft and bulb
Lupus erythematosus	Discoid, well-demarcated erythematous plaques with scale, plugging of follicles, and atrophy or thinning as a result of broken, fragile hair with acute flares (lupus hair)	Not applicable if scarred Short, broken (frayed) anagen hairs

Hairs are not firmly anchored because of an inner root sheath defect.

Typically, the child's hair is said to be slow growing, seldom requiring cutting. The hair over the occiput often is matted and sticky. The condition may wane with time, although adult-onset cases have been reported. The hair grows thicker and longer, and its pigmentation increases. Nonetheless, even in adulthood, it may pull out easily and painlessly. A hereditary factor may be involved, but most cases are sporadic. The diagnosis can be made from the history and examination, the painless *pull test* (when hair is growing normally, it usually hurts to pull it), and light microscopy to view the recovered hairs. Management is limited to reassurance.

### Trichorrhexis Nodosa

Trichorrhexis nodosa is a common abnormality of the hair shaft that becomes obvious under the light microscope, where the *nodes* resemble the effect observed when the ends of 2 brushes are pushed together. Most

often congenital, trichorrhexis nodosa results in breakage of hair and short stubble over the scalp; it may also be a genetic predisposition in some black patients, who experience hair breakage over large areas of the scalp and whose hair will not grow beyond a relatively short length. Trichorrhexis nodosa is usually accompanied by a history of hair straightening or repeated vigorous brushing and combing. Avoiding this kind of steady abuse and using a more gentle cosmetic approach can result in some gradual improvement. White and Asian individuals can experience the same difficulty, probably without congenital or familial relationship, and the breakage occurs most often at the distal end of the hair. White specks marking the nodes may appear after some physical and chemical injuries. Here again, a gentle approach and elimination of any noxious exposure are appropriate.

### Monilethrix

Monilethrix (beaded hair syndrome) is a condition in which scalp hairs have regularly spaced differences in

their circumference, suggesting a chain of beads. The cause is unknown but probably genetic, and no treatment is known. Although some degree of recovery may occur spontaneously, particularly after puberty or during pregnancy, this period is a long time to wait, inasmuch as hair breakage becomes obvious during infancy. Variable expressivity was noted in 3 kindreds in whom monilethrix was mapped to the type II keratin gene cluster at chromosome 12q13. Occasionally, associated problems (cataracts, brittle nails, faulty teeth) are suggestive of a more widespread ectodermal defect.

### Pili Torti

Pili torti simply means *twisted hair*, which indeed is the way this hair appears under the microscope. The color is “off,” and the hair is coarse and lusterless. It is as though straight and curly hair were competing for a place in the same strand. In cross-section, a straight hair appears round, and a curly hair appears oval. In pili torti, both configurations may be seen in a single strand, an abnormality that can be an important clue to Menkes kinky hair syndrome, an X-linked disease characterized by low serum copper, progressive cerebral degeneration with hypotonia and often with seizures, arterial degeneration, and osteoporotic bones.

### Alopecia Areata

Alopecia areata, most often seen as an acute problem, results in a sudden and total loss of hair in sharply circumscribed, round areas, often several centimeters in diameter, usually on the scalp, but possibly anywhere on the body where hair is found (Figure 126-1). Hairs at the periphery of an area are plucked easily and may be particularly colorless and thin. *Exclamation-point hairs* (broken hairs with a narrow bulb) may appear throughout the patch, which is sometimes salmon colored as a manifestation of the presumed inflammation seen histologically around the hair follicle. The fingernails may be pitted, possibly indicating a more extensive ectodermal problem.

Just a few patches of loss may be found, or a total absence of body hair (alopecia universalis) may occur, including eyebrows and eyelashes. The more extensive the loss and the younger the child, the less likelihood there is of a full recovery. The prognosis is best when the loss is less widespread and only 1 or 2 patches are present. Although the cause is unknown, some suggestion has been made of a T-cell-mediated autoimmune process against the anagen hair follicle, explaining recent interest in T-cell “biologics” as therapy, but thus far they have not been helpful. Occasionally, autoimmune antibodies are identified in patients who have alopecia areata when no other clinical evidence exists of autoimmune disease. An increased incidence of alopecia areata also occurs in persons who have acute autoimmune thyroid disease and vitiligo. The association with multiple genes suggests a susceptibility to alopecia areata, which manifests with various environmental factors.

About one-third of patients who have alopecia areata will regrow hair spontaneously in 6 months; for another one-third, hair will regrow within 5 years. For

**Figure 126-1** This 30-year-old man developed slow, expanding hair loss on the scalp 1 month earlier. Although a potassium hydroxide preparation was supposedly positive, he did not improve on topical ciclopirox shampoo and oral itraconazole. At a subsequent visit 1 month later, several new patches were noted, and the diagnosis was changed to alopecia areata. (Reprinted with permission from DermAtlas.org. Courtesy of Manoj Ram, MD.)

the remaining one-third, treatment is needed to stimulate hair growth.

Cortisone creams applied topically have been used with some success. In the older, more cooperative child, direct injection of corticosteroid into the scalp or eyebrow hair follicles can be effective, but the process is painful. The primary care pediatrician should seriously question the appropriateness of this procedure, carefully assessing the effect of the disease and of the treatment on the child, and should refer the patient to a dermatologist for consideration of this intervention. Excimer laser has shown some success even in children as young as 6 years of age with patchy alopecia areata.

Large areas (>50% scalp hair loss) that require steroid infiltration present obvious difficulty. Oral steroid therapy has the risk for serious complications but is occasionally used. Minoxidil 5% solution can be used twice daily as an adjunct to topical steroids for small, stubborn areas of alopecia. Latanoprost, a prostaglandin analog used to treat glaucoma, was noted by chance to promote the growth of eyelashes and is now commercially available; it and several newer agonists have had mixed results thus far in attempts to treat eyebrow and eyelash alopecia areata. There is no guarantee that if hair regrows in response to therapy it will persist, especially once treatment is stopped.

For extensive alopecia, some irritants (dinitrochlorobenzene immunotherapy and tars such as short-contact anthralin) and psoralen with ultraviolet A light (known as *PUVA therapy*) have been used. These agents should be used only in children older than 12 years and only by a knowledgeable dermatologist in controlled circumstances.

An oddity of alopecia areata is that when hair does regrow, it may initially be white. Eventually color returns, and casual observers cannot identify the formerly affected area.

The efficacy of treatment is difficult to assess because of the waxing-and-waning nature of alopecia areata. The National Alopecia Areata Foundation ([www.naaf.org](http://www.naaf.org)) offers education and support to families, and sponsors an annual children's camp. In counseling patients and their families, primary care pediatricians should remind them that the disease is nonscarring and that there is always the potential for full regrowth. Also, it is hoped that further elucidation of the genetics of alopecia areata will lead to more targeted therapies in the future.

### Telogen Effluvium

Telogen effluvium, the diffuse loss of hair in the telogen phase of growth, may be difficult to distinguish from diffuse alopecia areata. Actually the most common form of hair loss in children, telogen effluvium is what occurs in most infants at 6 to 8 weeks of age, probably as a result of the stress of birth, and it is the type of hair loss that can follow the stress of a febrile illness, surgery, or trauma. Presumably, the stress causes a synchronization of the hair follicles so that many of them reach the telogen phase simultaneously, reversing the normal 4:1 ratio of anagen to telogen. This is evident on the hair pull/pluck test, when the hairs of diffuse alopecia areata appear as dystrophic anagen rather than telogen hairs. Telogen effluvium is generally reversible.

### Androgenetic Alopecia

Androgenetic alopecia is a genetically determined loss of hair that begins most often with a receding hairline and some thinning over the vertex. It occurs most often in men but can happen to women. The fullest expression is most common in the mature adult, but pediatricians are confronted with the problem in 15% of adolescents older than 14 years. Hairs from affected follicles do not epilate easily on pulling, but they are shorter and finer as a result of normal pubertal androgen increase. No therapy is reliably effective, although topical minoxidil twice daily and hair transplant micrografts may help some individuals. Finasteride can be tried after 18 years of age with male patients but is contraindicated in female patients because of the possibility of genital defects in exposed male fetuses if a pregnancy occurs.

### Trichotillomania

Some children have a compulsive need to pull out their hair or even their eyebrows or eyelashes. Although not always of emotional significance, trichotillomania may provide a major clue to an underlying

**Figure 126-2** Trichotillomania in a 7-year-old boy.

psychosocial problem. The hair loss often appears in large, patchy, ill-defined patterns. The family structure and the interaction with siblings and parents and with friends at home and at school should be explored in an effort to find stressors. Consulting a psychiatrist should also be considered. The primary care pediatrician can paint the attacked areas with petroleum jelly in an attempt to frustrate the habit; however, without attention to the possibility of an underlying emotional issue, this approach is quite obviously temporary. Both imipramine and fluoxetine have been used successfully to control trichotillomania in some children.

The hair lost is that which is most accessible to the probing hand. In some cases, enough is pulled to simulate alopecia areata (Figure 126-2). The patient who eats hair may accumulate it in the stomach and create a trichobezoar (hairball), which may ultimately lead to acute intestinal obstruction or, most often, to the complaint of abdominal pain. A trichobezoar may be palpable as an abdominal mass and is demonstrable on a radiograph. Referral for either endoscopic or surgical removal is indicated.

### Traumatic Alopecia

Hair is fragile. It should be handled gently and without physical or chemical assault. In children, hair is probably best left alone, except for simple washing, combing, and cutting.

Constant teasing or straightening with heat or chemicals may seriously damage hair. Some hairstyles, particularly with barrettes, ponytails, braids, or cornrows, cause constant and prolonged traction, especially along the hairline. The hair may then fall out, accompanied by redness and inflammation, even with pustular involvement of the follicles. Generally, simply discontinuing the stress will help. In childhood, the hair will almost always return, although the regrowth can be slow. Injured hair follicles, whether from trichotillomania or simple traction, do not heal quickly, often taking 3 months or longer to return to an anagen phase.

### Tinea Capitis

Whenever a child has patches of alopecia or stubbly hair growth, even in the absence of crusting, scaling,

**Figure 126-3** A young boy admitted for asthma therapy was incidentally noted to have a scalp lesion. The scaling and focal alopecia suggested the diagnosis of tinea capitis. The child was successfully treated with griseofulvin.

redness, or other inflammatory signs, the physician should consider the possibility of tinea capitis, along with seborrheic dermatitis, atopic dermatitis, or psoriasis (Figure 126-3). Certainly, seborrhea and atopy are more common in children than fungal scalp infection; but particularly when alopecia is accompanied by local adenopathy, tinea capitis should be in the differential diagnosis. Obviously, if crusting, scaling, or redness is present, then the likelihood of alopecia areata is diminished because inflammation is not a symptom of that condition. In any event, the practitioner should perform a mycologic examination, looking particularly for the usual fungus, *Trichophyton tonsurans*. Clinically, the lesions tend to be more elevated than in other forms of tinea and may be characterized by black dots. In rare cases, the endothrix fungi *Microsporum canis* and *Microsporum audouinii* can invade the hair shaft and cause breakage and stubble. *M canis* tends to cause much more inflammation than does *M audouinii*. Endothrix fungal infections, but not *T tonsurans*, can produce a greenish fluorescence under Wood light in a darkened room.

On occasion, particularly with *M canis* or after treatment with an irritant, the affected area may become secondarily infected and seriously inflamed, requiring treatment with an antibiotic. Kerion, a delayed hypersensitivity reaction to the fungus, may develop, and if it is unchecked, the resultant scarring interferes with the regrowth of hair (Figure 126-4). Early diagnosis and treatment are therefore helpful.

Topical antifungal agents do not provide adequate treatment because the fungus is deep in the follicle. Oral griseofulvin had been the standard of care, but the usual course of 2 to 3 months of therapy may present difficulties with adherence in a young child. Several newer agents have the appeal of offering a

**Figure 126-4** A 2½-year-old boy with a kerion caused by chronic, progressive tinea capitis.

shorter course, despite their expense. The fungicidal drug terbinafine seems effective for tinea capitis when given for 6 weeks and is currently approved for children 4 years and older for this use by the US Food and Drug Administration; neither itraconazole nor fluconazole is approved, but they may be similarly safe for short courses in children. These agents certainly provide alternatives if griseofulvin therapy fails or is not tolerated, but they have not proved effective for *Microsporum tinea capitis*. Liquid itraconazole has been associated with diarrhea in children and with pancreatic adenocarcinoma in laboratory animals and should be avoided. Liver function should be tested if antifungal medications are used for longer than 12 weeks and at the start of therapy if any suggestion of preexisting liver disease exists. Oral prednisone tapered over 10 days may help rapidly decrease the tenderness and inflammation of a kerion and prevent a widespread id reaction. (For medication dosage information, consult the American Academy of Pediatrics *Red Book*.)

### Acrodermatitis Enteropathica

Acrodermatitis enteropathica, an autosomal-recessive disorder characterized by abnormal zinc absorption, has several important cutaneous manifestations, simulating, at times, psoriasis, epidermolysis bullosa, pyoderma, or candidiasis. Zinc deficiency can result in abdominal pain and diarrhea, as well as a wispy alopecia and dystrophic development of the fingernails, suggesting widespread ectodermal involvement. Oral zinc sulfate is the treatment of choice.

### Discoid and Systemic Lupus Erythematosus

Discoid lupus erythematosus can be disfiguring to the scalp and, with scarring, can cause a permanent loss of hair (Figure 126-5). Early treatment with topical or intralesional steroids may prevent scarring. Systemic

**Figure 126-5** This 43-year-old woman had an 11-year history of slowly progressive red scaly plaques with central scarring and hair loss in sun-exposed areas. A biopsy showed changes typical of discoid lupus. She was otherwise well and complained of itching of her feet where she had new lesions. She also had some asymptomatic erosions on the tongue and buccal mucosa. (Reprinted with permission from DermAtlas.org. Courtesy of Kosman Sadek Zikry, MD.)

lupus erythematosus can also cause alopecia, and the scalp itself can be erythematous; however, the loss of hair is generally temporary and does not involve the scarring characteristic of discoid disease.

## MANAGEMENT

Treatment for alopecia depends, of course, on the cause. Physicians are accustomed to seeing children who are being treated with antimetabolites wearing baseball caps or bandannas to hide their full or partial baldness from anagen arrest. A noticeable loss of hair from any cause may be disturbing to both patient and parent; therefore, the suggestion that the child wear a baseball cap or other concealing adornment may be appropriate. Even a hairpiece can be designed for a child. These steps serve in the interim while physicians attempt potentially helpful treatments or wait expectantly in circumstances in which their role is diagnostic and supportive. The possibility that hair will not fully regrow must be considered when loss follows high fever (telogen effluvium) or chronic toxicity (anagen effluvium); is accompanied by scarring; or occurs in the areas of nevi, aplasia cutis, or persistent hemangiomas. The pediatrician must talk this through with the child who is old enough and with the parents as well, exploring the emotional reaction and discomfort and, if recovery of hair is questionable, working with them to achieve an emotional balance consistent with reality and to adopt suitable coping mechanisms. In most instances, this goal is achievable, and the pediatrician should not back away from trying. The physician, sometimes frustrated by the lack of a practical, successful management regimen, should not forget

the value of a willing, listening ear. Plastic surgery expertise should be sought for consideration of hair transplants and scalp reduction (for scarred areas) when possible.

## WHEN TO REFER

- Rapid, diffuse hair loss
- Chronic, progressive, localized, or diffuse hair loss without regrowth
- Scarring alopecia
- Inability to grow hair as a result of breakage, loss, or abnormal texture of hair
- Appearance of scalp mass or plaque affecting localized hair loss

## TOOLS FOR PRACTICE

### Engaging Patient and Family

## Chapter 127 AMENORRHEA

Maria Trent, MD, MPH; Alain Joffe, MD, MPH

Amenorrhea is a common clinical complaint; its frequency varies based on the gynecologic age of the young woman (the number of months or years elapsed since menarche). For example, in a study of high school adolescent girls, the rates of girls who missed 3 consecutive menstrual periods in a single year were 12.5% in the first year after menarche and 5.4% after 7 postmenarchal years. Traditionally, amenorrhea has been classified as being either primary or secondary. Primary amenorrhea is defined as the failure to initiate

**BOX 127-1 Major Causes of Amenorrhea in Adolescent Girls by Organ System****CENTRAL NERVOUS SYSTEM**

- Familial-physiologic delay
- Systemic illness
- Developmental defects (eg, Kallmann syndrome)
- Laurence-Moon-Bardet-Biedl syndrome
- Prader-Willi syndrome
- Infiltrative disease
- Head trauma
- Sheehan syndrome (postpartum necrosis)
- Primary empty sella syndrome
- Irradiation
- Surgery
- Depression
- Drugs (eg, hormonal contraception, cocaine, phenothiazines)
- Psychological stressors
- Eating disorders (eg, anorexia nervosa)
- High-level athletic training with low weight for height (eg, female athlete triad)
- Psychosocial stress
- Central nervous system tumor (eg, prolactinoma)

**THYROID**

- Hyperthyroidism
- Hypothyroidism

**ADRENAL**

- Addison disease
- Cushing syndrome
- Late-onset congenital adrenal hyperplasia (21-hydroxylase deficiency)
- Tumor

**OVARIES**

- Gonadal dysgenesis
- Premature ovarian failure
- Radiation or chemotherapy
- Ovarian removal or destruction
- Polycystic ovary syndrome
- Tumor

**UTERUS**

- Pregnancy
- Uterine synechiae
- Congenital abnormalities (müllerian agenesis, androgen insensitivity)

**VAGINA, CERVIX, HYMEN**

- Agenesis
- Imperforate hymen
- Transverse septum

menstruation, whereas secondary amenorrhea refers to cessation of menses in an adolescent who has previously menstruated. Although some value can be found in knowing whether the absence of menses results from a disruption or lack of initiation, this distinction is of limited clinical utility because many diseases and clinical states cause both primary and secondary amenorrhea.

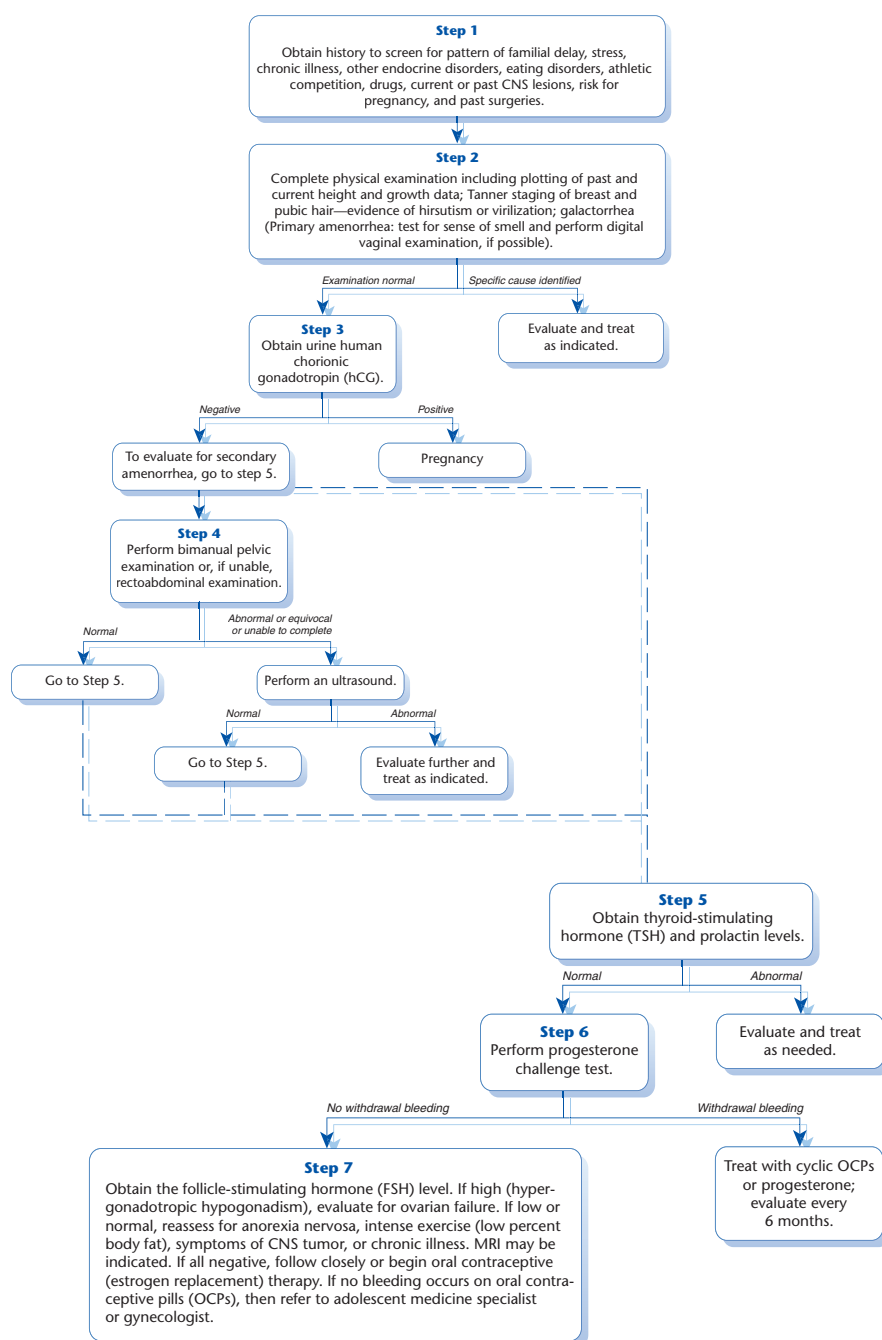

The mean age of menarche among girls in the United States has decreased slightly in recent years. In 1973, the average age of menarche was 12.76 years among participants in the National Health Examination Survey (NHES). Recent analyses using the combination of the NHES and National Health and Nutrition Examination Surveys (NHANES) have documented that the current average age of menarche in the United States is 12.54 years, with some variation by race or ethnicity. Further analyses from the NHANES data demonstrated that 90% of girls will have menstruated by age 13.75 years and that fewer than 10% menstruate before 11 years of age.

Amenorrhea is a symptom, not a disease, and has a variety of causes. The differential diagnosis for the patient with amenorrhea includes maturational (constitutional) factors, disorders of the central nervous system (CNS), adrenal and ovarian disease, congenital abnormalities of the reproductive tract (primary amenorrhea), thyroid disease, nutritional disorders, systemic illness, and pregnancy. Therefore, a thoughtful,

systematic approach to the patient who has a menstrual disorder usually identifies the cause. The major causes of amenorrhea are listed in Box 127-1.

Menstruation usually begins about 2 years after breast budding; however, the interval between these events can be as short as 6 months or as long as 4 years. Given this broad range of individual variation in the onset of puberty and menarche, the physician first must assess pubertal status, noting breast and pubic hair development. An evaluation is warranted if:

1. No signs of secondary sexual development are present by 14 years of age. In this instance, the evaluation should include an assessment for delayed puberty. (See Chapter 185, Puberty: Normal and Abnormal.)
2. Menarche has not occurred by 16 years of age even if the patient has experienced development of secondary sexual characteristics and growth has been normal.
3. Menarche has not occurred and the patient has been at Tanner stage 5 for at least 1 year or has had breast development for 4 years.
4. Three consecutive menstrual cycles are absent in a patient with signs of an eating disorder.
5. The patient has previously menstruated but has had amenorrhea for more than 6 months.
6. The patient has not had menses and has symptoms or stigmata of another disease process such as Turner syndrome.

**Figure 127-1** Evaluation of patients who have amenorrhea in whom secondary sex characteristics are present.

7. The patient has had menstrual cycles, has missed one period, and has had unprotected sexual intercourse in the interim. In this instance, the patient should be evaluated for pregnancy.

Gynecologic age is important when evaluating an adolescent who seems to have secondary amenorrhea. After the onset of menarche, many teenagers will menstruate sporadically; regular monthly cycles often are not established until 1 to 2 years after menarche. Clearly, the abrupt cessation of menstruation in a

teenager who has established regular cycles is of greater concern than the absence of menses for 3 to 4 months in a teenager who has a gynecologic age of 6 months to 1 year. The point at which the physician elects to pursue an evaluation depends on the anxiety of the patient and her family, the possibility of pregnancy, and the likelihood that a potentially serious disease is responsible for the amenorrhea. For a general approach to the evaluation of amenorrhea, see Figure 127-1.

## HISTORY

The history and physical examination are critical elements in the diagnostic approach. Although the adolescent should always be interviewed alone during the visit, many adolescent girls may have difficulty with the details of their own medical and family medical histories, making maternal involvement during the visit extremely useful. Mothers are able to provide detailed medical histories for their daughters from infancy to the present, the details of their own menstrual and medical histories, and usually that of first-degree female relatives. Finally, mothers are often acutely aware of behavioral factors within the home, such as a daughter's menstrual patterns, symptoms associated with menstrual cycles, consumption of pads or tampons, dietary and exercise patterns, stressors on the family and children, and the subtle development of physical features such as weight gain, acne, or hirsutism. Detailed discussions of personal lifestyle factors such as sexual activity should be conducted without the parent present. Use of the HEADDSS assessment (home situation, educational status of the patient, activities, diet, drug use, suicidality or depression, and sexuality or sexual behavior) facilitates this portion of the interview.

The hypothalamic-pituitary-ovarian axis of the adolescent is more sensitive to physical and psychological stress than is that of the adult woman. Stress, emotional upset, fever accompanying viral illness, and changes in weight or environment (eg, going away to college) all can induce amenorrhea. Comments about weight or body image may be a clue to anorexia nervosa. The history also should include questions about drug or medication use, including any forms of hormonal contraception that the patient may be using. Most women who develop amenorrhea while using combined estrogen-progesterone contraceptive methods resume menstruation within 6 months of discontinuing their use. Pregnancy should be the primary consideration in patients who have a history of sexual intercourse. Unfortunately, denial of sexual activity does not exclude pregnancy, inasmuch as many teenagers are reluctant to admit to something they believe will be met with condemnation from adults. Sudden cessation of menstruation is more likely to indicate pregnancy or stress as a cause, whereas a gradual cessation suggests polycystic ovary disease or premature ovarian failure. A history of uterine surgery or abortion raises the possibility of uterine synechiae. Given that many women are involved in sports, questions about exercise patterns or participation in athletics (frequency, duration, intensity) are essential. The physician must be sure to seek clues to any of the endocrine abnormalities (eg, galactorrhea), a history of past CNS insults (eg, meningitis), or symptoms of an intracranial tumor. The age at which the patient's mother and sisters first menstruated is also helpful information because such a pattern may be familial. Finally, chronic diseases such as inflammatory bowel disease or renal failure may be subtle in their early presentation; hence, questions aimed at uncovering these illnesses must be included in the review of systems.

## PHYSICAL EXAMINATION

Plotting of previous growth data (both height and weight) is essential. A short girl who has amenorrhea should prompt a search for the other physical characteristics of Turner syndrome. Diagnostic criteria for anorexia nervosa include loss of weight or failure to gain the weight expected with pubertal development. A complete physical examination, which in most cases will include a pelvic examination, should be performed. Obesity or excessive thinness can result in amenorrhea. Abnormalities of the visual field, smell, or other cranial nerve function; papilledema; or disturbances of reflexes suggest a CNS tumor. Hirsutism, a receding hairline, excessive acne, moon facies, striae, enlarged thyroid, or buffalo hump suggests an endocrine disorder. A webbed neck, short stature, or widely spaced nipples suggest Turner syndrome. Nipple discharge may indicate elevated prolactin levels, and lack of or scant pubic hair in a girl who has Tanner stages 3 to 4 breast development suggests androgen insensitivity syndrome.

A pelvic examination is essential to ensure the presence of normal internal and external female genitalia. An imperforate hymen or transverse vaginal septum prevents menstrual blood from escaping. If the hymenal opening is patent, then the examination should proceed to determine the presence of a normal vagina, cervix, and uterus. If the hymenal opening is very small, then the cervix and uterus can be palpated by means of a bimanual rectoabdominal examination. The size of the clitoris should be noted because clitoromegaly indicates the presence of excess androgens (eg, partial 21-hydroxylase deficiency). In the few cases in which a pelvic or rectoabdominal examination cannot be performed to determine the presence or absence of a uterus, an ultrasound may be necessary.

Although a pink vaginal mucosa indicates the presence of some degree of estrogenization, the patient's estrogen status can be assessed using a progesterone challenge, vaginal maturation index, or measurement of serum estradiol levels. The progesterone challenge is particularly useful because a positive result indicates an estrogen-primed uterus. The progesterone challenge is conducted by administering 10 mg of medroxyprogesterone acetate for 5 to 10 days. Any spotting or bleeding in the week afterward is considered a positive test. Some experts in the field recommend measuring follicle-stimulating hormone (FSH) levels before performing a progesterone challenge because some women who have hypergonadotropic amenorrhea will have a withdrawal bleed. A vaginal maturation index is performed by collecting cells from the upper lateral sidewall of the vaginal wall using a moistened cotton-tipped applicator, rolled on a glass slide, and fixed using the same technique in Papanicolaou smear preparation. Cytologic assessment will determine the number of parabasal, superficial, and intermediate cells present. Samples can be scored using Meisel's modified scoring system to interpret results in terms of estrogen and pubertal status.

## LABORATORY TESTS

For the girl with primary amenorrhea who has an unremarkable history, review of systems, and general physical examination, and no evidence of vaginal outlet obstruction, the next step is to determine, either by pelvic examination, ultrasound, or both, whether a uterus is present. If not, then karyotyping and serum testosterone levels should be determined to screen for müllerian agenesis or androgen insensitivity syndrome. If a uterus is present, then an evaluation comparable to that for secondary amenorrhea should be pursued.

Patients with primary or secondary amenorrhea who have a history of sexual activity should first be screened for pregnancy using a urine pregnancy test. If negative, then initial laboratory evaluation includes FSH, prolactin, and thyroid-stimulating hormone. Low or normal FSH levels are usually associated with physiologic delay, hypothalamic and pituitary causes of amenorrhea, and chronic illnesses. Elevated levels of FSH indicate ovarian failure. Follow-up testing in patients with elevated FSH levels should include karyotyping and screening for autoimmune endocrinopathies. Patients with amenorrhea and clinical evidence of androgen excess most likely have polycystic ovary syndrome (PCOS) or, less commonly, late-onset congenital adrenal hyperplasia (21-hydroxylase deficiency). Additional useful laboratory tests to assess for PCOS and other disorders associated with androgen excess include serum testosterone (total and free) and dehydroepiandrosterone (DHEA) and its sulfate (DHEA-S). Measurement of the first morning 17-hydroxyprogesterone levels is also indicated for patients with elevations in DHEA-S to further assess for late-onset congenital adrenal hyperplasia. If the patient has evidence of virilization (eg, clitoromegaly), or if the androgens are elevated in the tumor range, then adrenal and ovarian imaging are indicated, depending on the source of androgens. Isolated elevations of testosterone are suggestive of ovarian origin, whereas DHEA-S is suggestive of adrenal origin. (See also Chapter 164, Hirsutism, Hypertrichosis, and Precocious Sexual Hair Development.)

Imaging is indicated for other specific presentations of amenorrhea. Pelvic sonography is indicated if abnormalities are noted on bimanual examination or if bimanual examination is not possible. Magnetic resonance imaging of the pelvis is indicated for patients with possible congenital abnormalities. Dual-energy radiograph absorptiometry bone density evaluations should be obtained in girls with hypogonadotropic amenorrhea, given the association with low bone mineral density. Hypogonadotropic amenorrhea is commonly seen in patients with restrictive eating disorders, athletic amenorrhea, and ovarian failure.

## MANAGEMENT

Definitive recommendations for treatment of secondary amenorrhea depend on the underlying cause. When adolescent girls initiate puberty late, but progression through puberty seems normal and the findings of a thorough history and physical examination are also normal, the patient can be reassured that she

should anticipate menarche 2 to 3 years after the initiation of puberty. This probability is particularly true when family history suggests late menarche in first-degree female relatives. Regularly scheduled follow-up visits until menarche occurs are warranted. Any halt in development or absence of menarche by age 16 years merits an evaluation.

In patients with secondary amenorrhea and normal estrogen levels, medroxyprogesterone 5 to 10 mg for 12 to 14 days can be used every 1 to 3 months to stimulate withdrawal bleeding. For sexually active patients and patients with PCOS, treatment with combined contraceptives is indicated. Patients with PCOS may also benefit from additional medications to address underlying metabolic abnormalities or clinical findings associated with androgen excess (hirsutism and acne). In patients with low levels of estrogen, normalizing weight for height is important by addressing disordered eating and intensity of athletic training.

Although many pediatric practices provide gynecologic care, patients who cannot receive a thorough gynecologic assessment in the pediatrician's office should be referred to an adolescent medicine specialist or pediatric gynecologist for evaluation. Adolescent medicine physicians may be particularly well suited to address other developmental or endocrinologic issues that may also be present. Patients who have evidence of complicated endocrine disease; evidence of a CNS, adrenal, or androgen tumor; genetic disorder; eating disorder; or structural abnormality should also be referred to the appropriate specialty team for further evaluation and management.

## WHEN TO REFER

- The amenorrhea appears secondary to a chronic illness that the pediatrician is unable to manage
- The pediatrician feels uncomfortable performing a pelvic examination
- Long-term hormonal therapy is required
- The patient has an eating disorder
- Evidence exists of anatomic or chromosomal abnormality
- Evidence exists of a complicated endocrine disorder
- Evidence exists of a CNS, adrenal, or ovarian tumor
- The patient is pregnant and the pediatrician is unwilling or unable to provide comprehensive options counseling or referral for all options

## Chapter 128

# ANEMIA AND PALLOR

Alicia K. McFarren, MD; Adam S. Levy, MD

## INTRODUCTION

Anemia is a laboratory finding reflecting a decrease in red blood cell (RBC) mass below an age-appropriate normative value. Anemia may be associated with pallor, but it is more likely a silent symptom and detected only on routine screening studies. Pallor and anemia are not diagnoses; rather, they are signs and symptoms of an underlying disease process requiring a thorough evaluation by the primary care physician.

## DEFINITIONS AND CLINICAL MANIFESTATIONS

### Pallor

Pallor, derived from the Latin *pallere*, meaning “to be pale,” is a clinical sign associated with a variety of systemic illnesses resulting in a decrease in the amount of

oxygenated hemoglobin visible through the superficial and translucent layers of the skin and mucosa. Accurate assessment of pallor may be hindered by fluorescent lighting, dark skin color, jaundice, or cyanosis. Although a common finding in children with moderate to severe anemia, pallor does not necessarily indicate a low hemoglobin level. Sepsis may cause pallor resulting from a decrease in peripheral perfusion. Vasoconstriction from exposure to cold or febrile illnesses may also lead to pallor. Disorders that lead to an accumulation of fluid in the interstitium such as heart failure, hypoproteinemia, or myxedema can also result in pallor.

### Anemia

Anemia can be defined as a reduction in RBC number, RBC mass (hematocrit), or hemoglobin concentration. For each value, the lower limit of the normal range is defined as 2 standard deviations from the mean for age and gender (Table 128-1). Normal ranges for hemoglobin and hematocrit vary with age and gender. Racial differences exist as well. Black children on average have normal hemoglobin values that are approximately 0.5 g/dL lower than white and Asian children.

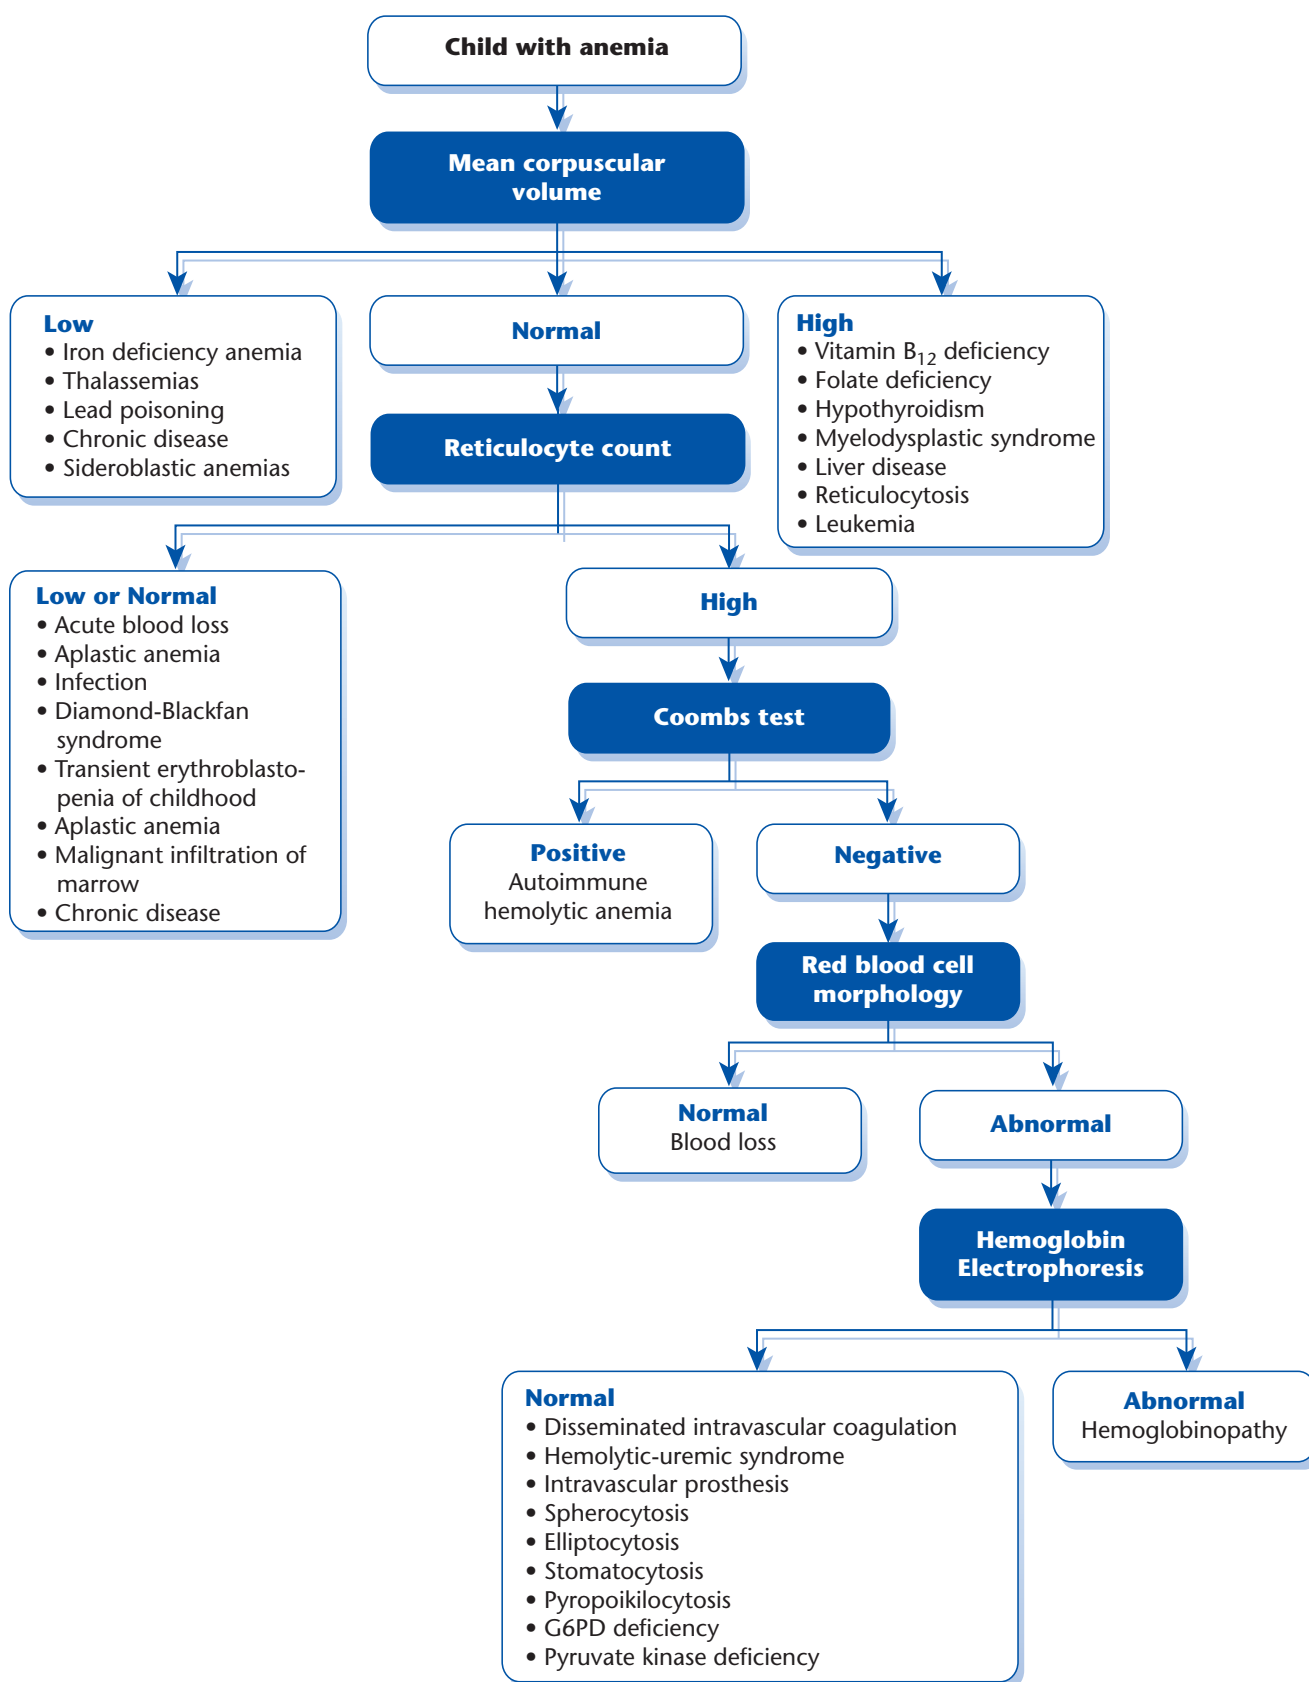

## CLASSIFICATION AND DIFFERENTIAL DIAGNOSIS

Anemias can be systematically evaluated based on RBC size (mean corpuscular volume [MCV]). Normal MCV values vary with age, but microcytic anemias generally have an MCV less than 70 fL, normocytic anemias have an MCV of 72 to 90 fL, and macrocytic anemias have an MCV of greater than 90 fL. Subclassification of anemias as microcytic, normocytic, and macrocytic will greatly reduce the differential diagnosis and limit the number of laboratory tests needed to attain the diagnosis. Figures 128-1 and 128-2 contain guidelines for a diagnostic approach to children and newborns with anemia. Box 128-1 lists the differential diagnoses of specific pathologic RBC features.

**Table 128-1** Mean Values for Hemoglobin, Hematocrit, and Mean Corpuscular Volume

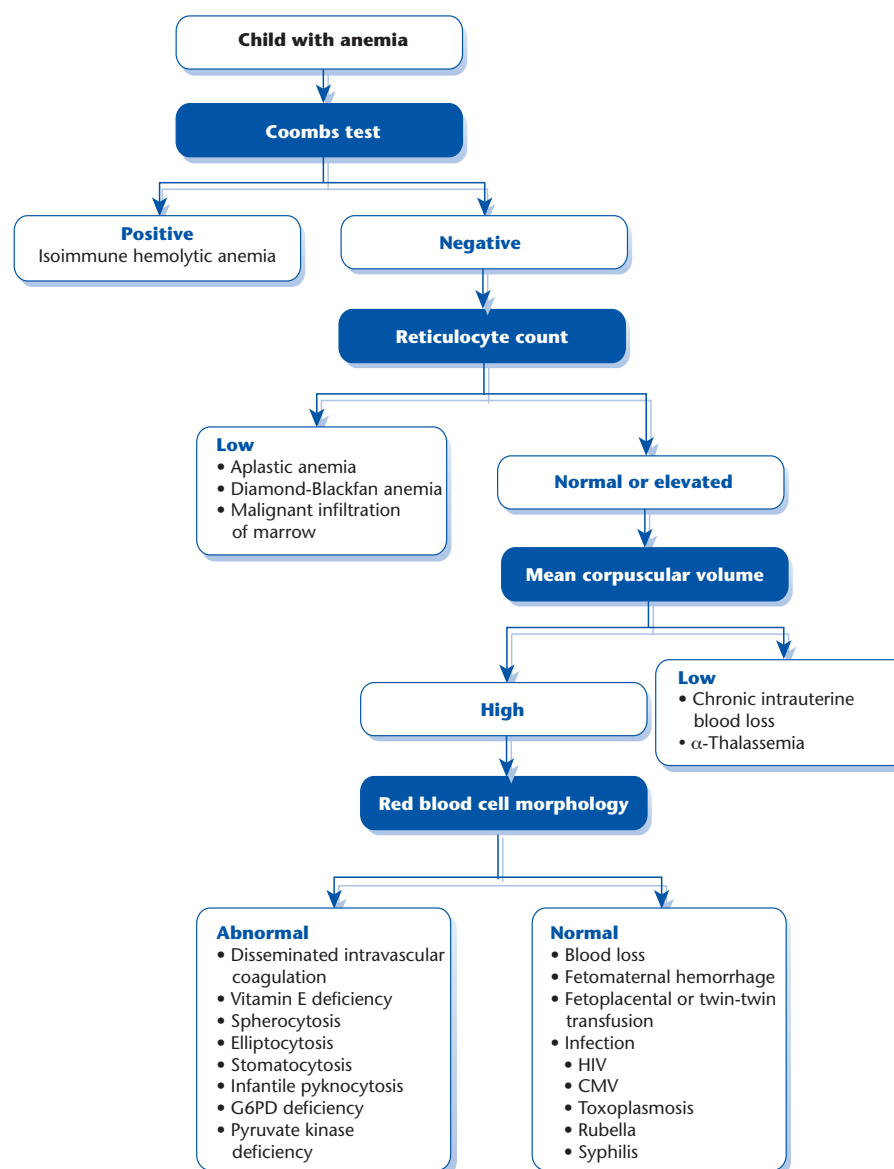

AGE	HEMOGLOBIN (g/dL)	HEMATOCRIT (%)	MCV (fL)
Cord blood	15.3	49	112
1 day	19.0	61	119
1 wk	17.9	56	118
1 mo	17.3	54	112
2 mo	10.7	33	100
3 mo	11.3	33	88
6 mo–2 yr	12.5	37	77
2–4 yr	12.5	38	79
5–7 yr	13	39	81
8–11 yr	13.5	40	83
12- to 14-year-old girls	13.5	41	85
12- to 14-year-old boys	14	43	84
15- to 17-year-old girls	14	41	87
15- to 17-year-old boys	15	46	86

### Microcytic Anemia

The differential diagnosis of a microcytic anemia is listed in Table 128-2, and the main causes are reviewed in detail here.

### Iron Deficiency

Iron deficiency is the most common cause of anemia in the United States. Iron deficiency may be attributed to poor iron intake, poor iron absorption, or blood loss. Full-term neonates are born with sufficient iron stores to last for the first 6 months of life. Iron deficiency is rare during this period. The incidence of iron deficiency anemia peaks at age 12 to 24 months and then

again in adolescence. The peak in childhood corresponds to the transition of children from human milk or iron-containing formulas to whole milk. Iron deficiency in adolescents is typically related to a poor dietary intake of iron, as well significant blood and iron loss in adolescent girls with menstrual bleeding.

In children of all ages, occult blood loss must be considered as a source for iron loss leading to deficiency. Blood loss may be acute, chronic, or intermittent. A thorough history should be obtained to rule out melena, hematochezia, tarry stools, and bloody or coffee-ground emesis. Stool guaiac tests for occult blood should be performed at several different times

**BOX 128-1 Differential Diagnosis of Specific Pathologic Red Blood Cell Features<sup>a</sup>****TARGET CELLS**

(Surface-to-volume ratio increased)

- Thalassemia
- Hemoglobinopathies
- Hemoglobin E disease
- Hyposplenism or postsplenectomy
- Hepatic disease
- Severe iron deficiency anemia
- Abetaproteinemia
- Lecithin or cholesterol acyltransferase deficiency

**SPHEROCYTES**

(Hyperdense cells with a decrease in surface-to-volume ratio and an increased mean corpuscular hemoglobin concentration)

- Hereditary spherocytosis
- Hemolytic anemia (autoimmune, ABO incompatibility, water dilution)
- Microangiopathic hemolytic anemia
- Hemoglobin SS disease
- Hypersplenism
- Burns
- After RBC transfusions
- Pyruvate kinase deficiency

**ACANTHOCYTES (SPUR CELLS)**

(Cells with 10–15 spicules that are typically irregular in length, spacing, and width; cells usually smaller than normal RBCs)

- Disseminated intravascular coagulation
- Microangiopathic hemolytic anemia
- Hyposplenism or postsplenectomy
- Hepatic disease
- Hypothyroidism
- Vitamin E deficiency
- Abetalipoproteinemia
- Malabsorption

**ECHINOCYTES (BURR CELLS)**

(Cells with 10–30 spicules that are typically of comparable size and distributed evenly)

- Dehydration
- Renal disease
- Hepatic disease
- Pyruvate kinase deficiency
- Peptic ulcer disease
- After RBC transfusion

**PYKNOCYTES**

(Hyperchromic RBCs with a decreased volume and distorted shape)

- Similar to acanthocytes and echinocytes

**BLISTER CELLS**

(Contain a clear area in RBCs that contains no hemoglobin)

- Hemoglobin SS disease
- G6PD deficiency
- Pulmonary emboli

**BASOPHILIC STIPPLING**

(Retention of RNA resulting in fine blue inclusions in the cytoplasm)

- Iron deficiency anemia
- Lead poisoning
- Hemolytic anemias
- Pyrimidine 5'-nucleotidase deficiency

**ELLIPTOCYTES**

(Elliptical-shaped cells)

- Hereditary elliptocytosis
- Iron deficiency anemia
- Thalassemia
- Hemoglobin SS disease
- Sepsis
- Megaloblastic anemia
- Malaria
- Leukoerythroblastic reaction

**TEARDROP CELLS**

(Microcytic and hypochromic cells that are in the shape of a teardrop)

- Normal finding in newborns
- Thalassemia
- Myeloproliferative diseases
- Leukoerythroblastic reaction

**SCHISTOCYTES**

(RBC fragments that result from trauma)

- Disseminated intravascular coagulation
- Hemolytic anemia and microangiopathic hemolytic anemia
- Kasabach-Merritt syndrome
- Purpura fulminans
- Hemolytic-uremic syndrome
- Uremia, glomerular nephritis, acute tubular necrosis
- Cirrhosis of the liver
- Malignant hypertension
- Thrombosis
- Thrombotic thrombocytopenia purpura
- Amyloidosis
- Chronic relapsing schistocytic hemolytic anemia
- Burns
- Connective tissue disorders

**BOX 128-1 Differential Diagnosis of Specific Pathologic Red Blood Cell Features<sup>a</sup>****STOMATOCYTE**

(Area of central pallor is more slit-like than round)

- Present in small numbers in normal individuals
- Stomatocytosis (hereditary)
- Thalassemia

**NUCLEATED RED BLOOD CELLS**

(Normal on a peripheral blood smear in the first week of life only)

- Normal newborns
- Significant bone marrow stimulation

- Congenital infections
- Hyposplenism or postsplenectomy
- Leukoerythroblastic reaction, particularly with severe infections and leukemias or metastatic tumors in the bone marrow
- Megaloblastic anemia
- Dyserythropoietic anemias

<sup>a</sup>Frequently, normal blood smears will contain abnormal-appearing RBCs that are simply an artifact of trauma during the blood draw or ex vivo processing of the blood.

*G6PD*, glucose-6-phosphate dehydrogenase; *RBC*, red blood cell.

Modified from Nathan DG, Orkin SH. A diagnostic approach to the anemic patient. In: *Nathan and Orkin's Hematology of Infancy and Childhood*. 5th ed. Philadelphia, PA: WB Saunders; 1998.

**Table 128-2 Classification of Anemia in Childhood**

<b>MICROCYTIC</b>	<b>NORMOCYTIC</b>	<b>MACROCYTIC</b>
Iron deficiency anemia	Infection	Megaloblastic anemias from B <sub>12</sub> or folate deficiency
Lead poisoning	Acute blood loss	Reticulocytosis
Copper deficiency	Renal disease	Postsplenectomy
Malnutrition	Connective tissue disorder	Myelodysplastic syndrome
Chronic disease	Hepatic disease	Aplastic anemia
Thalassemia	Hemolysis	Fanconi anemia
Hemoglobin E trait	Hypersplenism	Diamond-Blackfan syndrome
Sideroblastic anemia	Malignancy	Pearson syndrome
Atransferrinemia	Aplastic anemia	Dyskeratosis congenita
Inborn errors of metabolism	Dyserythropoietic anemia	Paroxysmal nocturnal hemoglobinuria
	Drugs	Down syndrome
		Hypothyroidism
		Hepatic disease, jaundice
		Drugs (eg, phenytoin, methotrexate)

to capture any intermittent bleeding. Common causes of gastrointestinal bleeding include gastric and duodenal ulcers, Meckel diverticulum, polyps, hemorrhoids, and gastritis. Signs and symptoms of inflammatory bowel disease should also be considered in the history and physical examination. Patients with iron deficiency anemia have symptoms similar to those in other forms of anemia, including pica as a craving for ice.

When iron deficiency is sufficient to cause anemia, other abnormalities may be seen on routine laboratory testing. In addition to being microcytic, the RBCs will be hypochromic, with target cells and elliptocyte forms visible on the peripheral blood smear. These features and a low reticulocyte count are sufficient to make the diagnosis of iron deficiency anemia. In many instances, further testing is not necessary but may be helpful in some settings. Serum iron and ferritin levels are low, whereas the total iron-binding capacity is

elevated. Many children also have an elevated platelet count.

When a primary care physician is treating a child with hypochromic, microcytic anemia found on a routine screening blood cell count, and a history of poor iron intake or excessive milk intake is elicited, a reasonable approach would be to give a trial of supplemental iron (6 mg/kg of elemental iron per day divided into 2 or more doses) rather than to draw additional blood for biochemical analysis. The reticulocyte count should increase within 5 to 7 days once therapy is initiated. Assuming the dietary deficiency is corrected, supplemental iron should continue for 2 to 3 months after the hemoglobin concentration has normalized to replenish iron stores fully. For patients with a hypochromic microcytic anemia who do not seem to be at risk based on diet alone, and for those who do not respond to supplemental iron, additional testing is required. Iron deficiency, although common, is still

abnormal, and the etiology of the deficiency should be clearly defined.

### Thalassemias

The thalassemias are a heterogeneous group of disorders of hemoglobin production. The  $\alpha$ -thalassemias have deficient production of the  $\alpha$  chain, and the  $\beta$ -thalassemias have deficient production of the  $\beta$  chain. In either case, the excess of one chain relative to the other results in precipitation and destruction of the RBCs.

**$\beta$ -THALASSEMIA.** Thalassemia minor (or thalassemia trait) is common among black patients and results from a mutation of 1 of the 2 genes on chromosome 11 encoding for the  $\beta$ -chain. When only 1 gene is affected, a mild decrease in  $\beta$ -chain production occurs, resulting in a mild anemia. Patients with thalassemia trait frequently have a hypochromic, microcytic anemia found on a routine complete blood count, similar to patients with iron deficiency anemia. Target cells are also common to both diseases. However, patients with thalassemia trait usually have an increase in the number of RBCs, whereas patients with iron deficiency commonly have a decrease in RBC number. A hemoglobin electrophoresis may also be helpful in diagnosing thalassemia trait. Both the hemoglobin F and hemoglobin A<sub>2</sub> levels are commonly elevated. Although treatment is not necessary, diagnosing thalassemia trait is important so that appropriate genetic counseling may be offered to patients and families.

**THALASSEMIA MAJOR.** Thalassemia major (Cooley anemia) results from defects in both  $\beta$ -globin genes and manifests as a severe hemolytic anemia. Marked compensatory erythropoiesis causing expansion of the medullary space results in a prominence of the cheeks and frontal bossing. Long-term transfusion therapy is required for these patients, and immediate referral to a hematologist is necessary.

**$\alpha$ -THALASSEMIA.** Each chromosome 16 contains 2 identical genes (4 genes total) for the  $\alpha$  chain. Abnormalities in these genes, most commonly seen in blacks and Asians, result in  $\alpha$ -thalassemia. When 1 gene is affected, the patient will be asymptomatic, with little or no abnormality on routine testing.  $\alpha$ -Thalassemia trait is the result of a mutation in 2 genes. Patients with  $\alpha$ -thalassemia trait are also asymptomatic. They have laboratory findings similar to patients with  $\alpha$ -thalassemia trait or iron deficiency (microcytic, hypochromic) anemia. However, unlike  $\alpha$ -thalassemia trait, the anemia is usually less severe, and the hemoglobin electrophoresis is normal. The diagnosis is based on the findings of a microcytic, hypochromic mild anemia in patients of Asian or black descent with a normal electrophoresis and no evidence of iron deficiency. Molecular genetic testing of *HBA1* and *HBA2* detects deletions in about 90% and point mutations in about 10% of affected individuals. For purposes of genetic counseling, the typical Asian genotype, with both abnormal genes on the same chromosome, is of more concern than the usual genotype in black patients, with 1 abnormal gene on each chromosome 16. When 3 of the 4 genes are affected, hemoglobin H disease is the result. Patients

with hemoglobin H disease may be asymptomatic but on laboratory testing show a moderate to severe anemia (hemoglobin, 7–10 g/dL). The anemia is microcytic and hypochromic, with RBC fragments visible on review of the peripheral blood smear. A hemoglobin electrophoresis shows 5% to 30% hemoglobin H (hemoglobin consisting of 4  $\beta$  chains). In the newborn period, hemoglobin Barts may be detected, which consist of 4 gamma chains. With mutations in all 4 genes, no normal hemoglobin is made, and unless the diagnosis is made prenatally to allow for intrauterine transfusions, the fetus will die with hydrops fetalis.

### Lead Poisoning

Any measurable lead in the plasma is abnormal, but clinically significant lead poisoning occurs at lead levels higher than 10 mcg/dL, and levels higher than 5 mcg/dL deserve attention. In most instances, lead poisoning is diagnosed on routine screening tests. The anemia in lead poisoning is microcytic and hypochromic, similar to iron deficiency. However, intense basophilic stippling of the RBCs may also be observed. Lead inhibits the insertion of iron into the protoporphyrin ring, thus inactivating heme synthesis and leading to an accumulation of free erythrocyte protoporphyrin, the levels of which can be elevated in both iron deficiency and lead poisoning.

### Chronic Inflammation

Chronic illness may be associated with anemia, likely the result both of decreased production and shortened RBC survival. Iron flow from the reticuloendothelial cells to the erythroblasts may also be diminished, resulting in a hypochromic, microcytic anemia. Anemia of chronic disease can be associated with malignancies, autoimmune diseases, renal failure, and chronic infections. Frequently, RBCs in chronic disease are normocytic and normochromic, but microcytic and hypochromic anemias are seen as well. The hemoglobin typically is in the range of 7 to 10 g/dL with a normal to low reticulocyte count.

### Sideroblastic Anemias

The sideroblastic anemias, caused by the retention of iron in the mitochondria of immature erythrocytes, are rare forms of anemia in childhood. Acquired sideroblastic anemia is a disease primarily of adulthood, whereas inherited forms of the disease occur in childhood.

### Normocytic Anemia

Normocytic anemia is defined as a decreased circulating RBC mass with an MCV in the appropriate range for age. As noted previously, the distinction of age-appropriate normative values is well established and important to consider lest the physician misinterpret a child's results and pursue an unnecessary evaluation (see Table 128-1).

The differential diagnosis of normocytic anemia (see Table 128-2) is broad and can be divided into primary hematologic disorders or systemic disorders with secondary anemia. Primary hematologic causes of normocytic anemia include early iron deficiency

anemia, aplastic anemia and other bone marrow failure syndromes, and hemolytic anemias (most commonly sickle cell disease). Systemic disorders with secondary normocytic anemia include anemia of chronic disease, systemic infection, acute blood loss, renal failure, and other disorders. The physician can also classify normocytic anemia as a disorder of decreased RBC production or increased RBC destruction. Whichever way is chosen to develop a diagnostic algorithm, approaching the diagnosis of anemia in a structured way that can consistently consider the broad range of diagnostic possibilities is useful.

### **Primary Hematologic Causes of Normocytic Anemia**

For many patients, the diagnosis of anemia is made on routine screening. Iron deficiency anemia is the most common cause of nutritional anemia in childhood discovered by routine screening. Although the classic indices for iron deficiency anemia include a low MCV and a high red cell distribution width, early iron deficiency anemia may appear as a normocytic anemia. A reticulocyte count will be lower than expected for a patient with anemia because RBC production will be decreased. Iron studies should corroborate the diagnosis of iron deficiency anemia, but a trial of supplemental iron should be both diagnostic and therapeutic.

Aplastic anemia and bone marrow failure syndromes can result in normocytic anemia as a result of decreased RBC production. Examples include congenital or acquired aplastic anemia, transient erythroblastopenia of childhood, pure red cell aplasia (Diamond-Blackfan anemia), and viral infections (eg, parvovirus, Epstein-Barr virus).

Bone marrow infiltration from a malignant process (either leukemia or metastatic solid tumors) can result in decreased RBC production and cause a normocytic anemia. Again, the reticulocyte count will be lower than expected for the degree of anemia. Abnormalities in the white blood cell count and platelet count may also be noted. Immature cells may be noted on review of a peripheral blood smear. Evidence of hemolysis and increased RBC turnover should be absent.

Hemolytic anemias result from RBC membrane defects (eg, hereditary spherocytosis, elliptocytosis), enzyme defects (eg, glucose-6-phosphate dehydrogenase [G6PD] deficiency, pyruvate kinase deficiency), hemoglobin defects (eg, sickle cell disease, thalassemias), and autoimmune hemolytic anemias. In general, the hemolytic anemias are characterized by an elevated reticulocyte count and evidence of increased RBC destruction (elevated serum bilirubin level). A patient with a personal or a family history of early cholecystectomy or intermittent jaundice may suggest a familial hemolytic anemia. Obtaining the complete blood count results of immediate family members may help confirm the diagnosis. Although routine newborn screening will identify patients with sickle cell disease born in the United States, children born in areas without routine screening may well have their sickle cell disease diagnosed later in life.

Rarely, normocytic anemia may result from a combination of a microcytic anemia (iron deficiency) and a

macrocytic anemia (folate deficiency). The MCV is a mean and, as such, 2 populations of RBCs may average out to a normal MCV.

### **Systemic Causes of Normocytic Anemia**

Acute blood loss will result in a normocytic anemia. Patients with chronic blood loss (eg, gastrointestinal bleeding) will likely become iron deficient and develop a microcytic anemia. However, in the early stage of the process, the patient will have normocytic RBCs. Testing the stool for occult blood is indicated in the evaluation.

Anemia of chronic disease is a poorly understood but well-recognized cause of normocytic anemia in children and adults. Anemia of chronic disease can be associated with a variety of illnesses, including rheumatologic conditions, systemic infections, endocrine dysfunction, liver failure, lung disease, and renal disease.

### **Evaluation of Normocytic Anemia**

In general, normocytic anemias that are nonresponsive to supplemental iron and not clearly associated with a systemic illness warrant referral to a pediatric hematologist. A reticulocyte count and review of the peripheral blood smear are indicated for every child with normocytic anemia referred to a hematologist. The smear may help identify morphologic features to aid in the diagnosis (eg, spherocytosis, sickle cells) or reveal evidence of hemolysis (schistocytes, RBC fragments).

The percentage reticulocyte count must be considered within the context of the patient's hemoglobin level and hematocrit. A high percentage reticulocyte count is expected in a child who can mount an appropriate response to anemia. An apparently normal reticulocyte percentage (1.1%–3.5%) in a child with severe anemia is actually relatively lower than it should be to compensate for the anemia. For this reason, the reticulocyte index is a useful calculation: the reticulocyte count multiplied by the ratio represented by the patient's hematocrit divided by the normal hematocrit.

A relatively low reticulocyte count (<1%) suggests decreased RBC production. The primary care physician must then consider aplastic anemia, malignancy, transient erythroblastopenia of childhood, and other causes of bone marrow suppression. A bone marrow aspirate and biopsy are rarely indicated but must be considered to rule out malignancy, especially when more than a single blood cell line is abnormal.

An elevated reticulocyte count suggests that the bone marrow is compensating for blood loss either from hemolysis or from hemorrhage. Causes of blood loss must be considered. Patients with an elevated reticulocyte count and an elevated bilirubin level likely have ongoing hemolysis. A positive Coombs test (direct antiglobulin test) suggests an autoimmune hemolytic anemia. Without evidence of an autoimmune process, hemoglobinopathies (sickle cell disease and variants and thalassemias) must be evaluated by hemoglobin electrophoresis.

Other specialized assays may define specific RBC disorders that result in hemolysis. G6PD deficiency,

which is X-linked, is the most common enzyme defect in males. Many variants have been found, and the assay may be falsely negative in patients with a high reticulocyte count immediately after a hemolytic crisis. Families need to be educated regarding the triggers for hemolysis in G6PD deficiency, including a variety of medications, infections, exposure to mothballs, and, for some variants, fava beans (favism). A positive osmotic fragility test helps confirm the diagnosis of hereditary spherocytosis and should be considered in patients with RBC morphology consistent with the diagnosis.

### Macrocytic Anemias

Macrocytic anemias in childhood are extremely rare and are typically the result of deficiencies in folate or vitamin B<sub>12</sub>. Folate deficiency can be associated with inborn errors of metabolism, poor dietary intake, increased utilization in patients with hemolytic anemias, malabsorption, and drugs that inhibit folate metabolism (methotrexate). Vitamin B<sub>12</sub> deficiency may be caused by inborn errors of metabolism, poor dietary intake, and malabsorption. In cases of significant deficiencies, these anemias can be quite severe, with an MCV between 100 and 140 fL. In addition to normochromic macrocytic RBCs, hypersegmented neutrophils may be visible on the peripheral blood smear. Serum folate and B<sub>12</sub> levels may help confirm the diagnosis, but the underlying cause of the vitamin deficiency must be determined.

A macrocytic anemia in a child is always concerning for an underlying disorder in bone marrow production. Myelodysplasia, early aplasia, and leukemia may all manifest as macrocytosis with or without anemia. In the absence of a clear B<sub>12</sub> or folate deficiency, a referral to a hematologist is warranted for assessment of macrocytosis to rule out myelodysplasia or malignancy.

### Anemia of the Newborn

The differential diagnosis of anemia in a newborn is distinctly different from that in older children. Peripartum hemorrhage and maternal factors, such as alloantibodies, are important in deciphering neonatal anemias. Iron deficiency in the newborn period is quite rare. Anemias with similar origins may also be displayed differently in infants and children.

Table 128-1 lists the normal hematologic parameters for infants and children. Hematologic parameters in children evolve over the first couple of months of life. Typically, a normal hemoglobin level in a term newborn is approximately 19 g/dL. The hemoglobin concentration falls gradually to a nadir of 10 to 11 g/dL by 8 to 12 weeks of age. This nadir, termed *physiologic anemia of the newborn*, is more pronounced in preterm infants with nadirs as low as 7 to 8 g/dL. Despite the low nadir, transfusions are necessary only if the anemia is uncompensated, although early supplementation with iron is usually indicated.

When considering the differential diagnosis of anemia in newborns, classifying the cause of the anemia into 1 of 3 broad groups is helpful: (1) blood loss, (2) hemolysis, or (3) decreased production. Blood loss

may occur at any time during a pregnancy. Common causes include fetomaternal transfusion, twin-to-twin transfusion, placental abruption, placenta previa, and internal hemorrhage (eg, intraventricular hemorrhage, cephalohematoma, caput succedaneum). The Betke-Kleihauer test detects the presence of fetal RBCs in the mother. Fetal cells can be detected in the circulation of 50% of pregnancies; however, rarely is the hemorrhage significant enough to cause anemia in the newborn. Mothers who are blood type O with infants who are not type O may have a false-negative Betke-Kleihauer test result.

At least 15% of monochorionic twins develop significant twin-to-twin transfusions, with differences in hemoglobin concentrations of 5 g/dL or more. At birth, the donor twin typically is smaller and may have pallor, oligohydramnios, and even shock. Polycythemia, polyhydramnios, and congestive heart failure may be present at birth in the recipient twin.

The clinical manifestation of neonatal anemia from blood loss is dependent on the severity and rapidity of the blood loss. Infants with chronic blood loss throughout pregnancy may have pallor and microcytic, hypochromic anemia but appear otherwise well and hemodynamically stable. Infants with acute blood loss may have pallor, tachypnea, tachycardia, hypotension, and decreased tone. A normocytic, normochromic anemia with a reticulocytosis is detectable soon after birth.

The most common cause of hemolytic anemia in the newborn is isoimmune hemolytic anemia caused by an incompatibility in maternal and fetal RBC antigens, including Rh, ABO, and minor blood groups. Mothers who are Rh negative may become immunized against the Rh antigen when pregnant with an Rh-positive fetus. During subsequent pregnancies, if the fetus is Rh positive, then maternal anti-Rh antibodies will readily cross the placenta and destroy the Rh-positive RBCs in the fetus. In utero and perinatal hemolysis may be rapid and severe, resulting in life-threatening hemolysis and hyperbilirubinemia. However, with the prenatal administration of Rh immune globulin to Rh-negative mothers, life-threatening Rh incompatibility is rare today. In cases of hemolytic anemia from ABO or minor blood group antigen incompatibility, the mechanism of immunization and hemolysis is similar to Rh incompatibility, but the hemolysis is rarely severe. Hemolytic anemia in the newborn may also occur as a result of maternal drug use and neonatal infections, including bacterial sepsis, cytomegalovirus, toxoplasmosis, herpes, and rubella. Microangiopathic hemolysis may occur in infants with thrombi, disseminated intravascular coagulation, and Kasabach-Merritt syndrome (multiple cavernous hemangiomas).

Hemolysis from hemoglobinopathies rarely causes symptomatic anemia in newborns. Anemia from  $\beta$  chain defects (eg, sickle cell disease,  $\beta$ -thalassemias) may not appear until later in infancy when the hemoglobin concentration is more dependent on  $\beta$ -chain production.  $\alpha$ -Thalassemia major will manifest as erythroblastosis fetalis in the newborn period. RBC membrane and enzyme defects may be apparent at birth but more commonly appear later in the newborn period.

RBC production deficiencies are rare in the newborn period and are typically the result of infection or drugs. Diamond-Blackfan anemia is a rare congenital pure RBC precursor aplasia. However, affected patients are typically not anemic until 3 to 12 months of age. Congenital leukemias and osteopetrosis may also result in deficient RBC production but are also typically associated with disorders in the other cell lines and are extremely rare.

## EVALUATION

Anemia is frequently identified in the first or second year of life and in adolescence on routine screening performed by primary care physicians. By using information obtained from a thorough history and physical examination, as well as results of routine laboratory studies, most causes of anemia can be accurately diagnosed in the primary care physician's office. Diseases leading to anemia and pallor in infants and children are listed in Table 128-2, Figure 128-1, and Figure 128-2.

## History

Many children with anemia are asymptomatic and have their condition diagnosed only on routine screening evaluations. Nonetheless, a thorough history may help identify patients most at risk for developing anemia, as well as help identify the cause of an existing anemia. Demographic factors such as age, gender, and ethnicity will identify risk groups for specific types of anemia. Toddlers and adolescent girls account for most cases of iron deficiency anemia. Blacks are at greatest risk for sickle cell anemia, whereas the thalassemias occur primarily in patients of Mediterranean and Southeast Asian descent. A diet history is crucial in identifying children most likely to develop iron deficiency anemia. Sulfa drugs can produce a hemolytic anemia in patients with G6PD deficiency. Many common acute bacterial and viral infections

may result in a mild anemia from decreased RBC production or increased RBC destruction, or both. Anemias resulting from such infections are typically short-lived but are commonly the cause of abnormalities identified on routine screening. Acute or chronic blood loss (or both) should be considered in all patients with anemia. Common sites of blood loss in otherwise asymptomatic patients include the gastrointestinal tract for all patients and the genitourinary tract for female patients. Anemia may be the benign manifestation of an underlying systemic disease such as autoimmune disorders and may be associated with signs of systemic illness (fevers, weight loss, among other signs). Finally, a family history may help guide the workup for a patient with anemia. In addition to a family history of hemoglobinopathies, a history of jaundice during systemic illnesses, cholecystectomy at a young age, or splenectomy may suggest a hereditary hemolytic anemia. Historical factors worthy of note in evaluating an anemic patient are listed in Table 128-3.

## Physical Examination

Infants and toddlers may experience fatigue, irritability, pallor, increased periods of sleep, poor feeding, and failure to thrive. Older children and adolescents may experience fatigue, pallor, exercise intolerance, dizziness, headaches, shortness of breath, or palpitations. However, most mild to moderate anemias in childhood are asymptomatic because they develop slowly over time, and patients are usually well compensated. In fact, seeing a child for a routine physical examination only to find out later that routine laboratory studies reveal anemia is not uncommon.

Pallor is the classic physical examination finding suggestive of anemia but is rare in mild anemias and frequently only seen reliably with hemoglobin concentrations less than 8 g/dL. Pallor may be more easily identified in the nail beds, mucosa, conjunctiva, and

**Table 128-3** Pertinent Historical Factors in the Diagnosis of Childhood Anemia

Age	Nutritional anemias are rare in infancy in term infants but are more common in infants born preterm, as well as in school-aged children and adolescents. Significant anemia diagnosed in the first 6 months of life in a term infant is most likely a congenital anemia.
Gender	G6PD is an X-linked disorder.
Race and ethnicity	Hemoglobin S and C are more common among patients of African descent. $\alpha$ -Thalassemias are most common in patients of African or Asian ancestry. $\beta$ -Thalassemia syndromes are more common in patients from the Mediterranean.
Nutrition	Sources of iron, folate, B <sub>12</sub> , and vitamin E should be documented. A history of pica suggests iron deficiency.
Medications	Phenytoin and methotrexate can induce a megaloblastic anemia. Oxidants can induce hemolytic anemias.
Family history	Document a history of anemia, jaundice, gallstones, cholecystitis, splenomegaly, splenectomy, or hemolytic crisis, which may suggest an inherited hemolytic anemia.
Infection	Infections may induce hemolysis or red blood cell hypoplasia or aplasia (parvovirus B19), whereas hepatitis may induce aplastic anemia.
Gastrointestinal	The gastrointestinal tract is a common source of blood loss. Nutritional deficiencies may result from malabsorption syndromes.

G6PD, glucose-6-phosphate dehydrogenase.

Modified from Nathan DG, Orkin SH. A diagnostic approach to the anemic patient. In: *Nathan and Orkin's Hematology of Infancy and Childhood*. 5th Ed. Philadelphia, PA: WB Saunders; 1998. Copyright © 1998, Elsevier, with permission.

palmar creases than in a cursory examination of the skin. Splenomegaly, scleral icterus, and jaundice in the setting of anemia are highly suggestive of a hemolytic process. In chronic hemolytic anemia such as thalassemia, frontal bossing and maxillary prominence are indicative of the marrow expansion necessary to keep pace with ongoing hemolysis. Leukemia or lymphoma may manifest as an anemia associated with focal lymphadenopathy and hepatosplenomegaly. Regardless of the cause of the anemia, a mild to moderate decrease in RBC mass may result in a pulmonary valve flow murmur, whereas more severe anemias may be associated with signs and symptoms of congestive heart failure. Compensated anemia usually refers to anemia associated with sufficient cardiovascular compensation to preserve normal oxygen delivery to tissues. Patients in whom the anemia develops or persists over a long period may have hemoglobin concentrations less than 6 g/dL but no signs or symptoms of anemia other than pallor. Cardiac stroke volume is increased, allowing patients to maintain normal oxygen delivery to tissues with normal or near-normal heart rates. Patients who lose blood more rapidly, from hemolysis or hemorrhage, may not have time for compensatory mechanisms to maintain tissue perfusion and oxygenation. Tachycardia is an early sign, followed by orthostasis, headache, dizziness, and hypotension, all of which are reasons to hospitalize a patient with anemia.

### Laboratory Findings

In addition to a determination of the hemoglobin level and hematocrit, which may be done exclusively in some practice settings, RBC morphology and reticulocyte count should be assessed. Anemias may be classified by RBC size as determined by the MCV and by RBC production as determined by the reticulocyte count. An elevated reticulocyte count implies bone marrow compensation for chronic blood loss or hemolysis, whereas a low reticulocyte count may suggest impaired RBC production or acute blood loss. Although not necessary in the initial diagnosis of all patients with anemia, iron studies may be performed and erythrocyte sedimentation rate, serum bilirubin, and serum lactate dehydrogenase levels may be assessed easily in most practice settings and may provide clues to the cause of the anemia. The mean corpuscular hemoglobin (MCH) and mean corpuscular hemoglobin concentration (MCHC) are generally of minimal value in the classification and diagnosis of an anemia. Changes in the MCH typically parallel changes in the MCV. The MCHC is a measure of RBC hydration status. Higher MCHC values ( $>35$  g/dL) are seen in dehydrated red cells associated with spherocytosis, and low MCHC values may be seen in iron deficiency.

### TREATMENT

Treatment of a compensated anemia will be dictated by the cause of the anemia. Patients with uncompensated anemia should be admitted to the hospital for observation and possible transfusion. Effective treatment of the anemia is best accomplished by treating

the underlying disorder. A substantial number of patients with a microcytic anemia or a normocytic anemia have early iron deficiency anemia, and a course of supplemental iron is appropriate. However, for patients with anemia that is nonresponsive to nutritional supplements and not clearly related to a systemic illness, referral to a pediatric hematologist is warranted. Referral to a pediatric oncologist is also warranted for management of most macrocytic anemias that are not related to nutritional deficiencies. Specific treatment will be predicated on the underlying hematologic disorder.

### WHEN TO REFER

- Hemoglobin level less than 8 g/dL or hematocrit less than 25%
- Anemia of unknown origin
- Anemia is associated with disorder in white blood cells or platelets
- Diagnosis of hemoglobinopathy or RBC membrane defect is suspected or confirmed

### WHEN TO ADMIT

- Profound anemia (hemoglobin level  $<5$ )
- Uncompensated anemia or anemia associated with a rapidly dropping hemoglobin level
- Anemia in an ill child

## Chapter 129

# ANXIETY

Lawrence S. Wissow, MD, MPH

### INTRODUCTION

Symptoms of anxiety affect many children, including a large number whose symptoms do not rise to the level of a disorder. At some stages and in some circumstances, a certain level of anxiety is developmentally appropriate (eg, stranger anxiety in late infancy or anxiety in anticipation of a painful medical procedure). However, from 6% to 20% of youth will meet diagnostic criteria for an anxiety disorder at some time during childhood, with approximately half experiencing impairment of daily functioning. Anxiety disorders (generalized anxiety disorder, panic disorder, separation anxiety disorder, agoraphobia, social phobia, post-traumatic stress disorder [PTSD], obsessive-compulsive disorder [OCD], specific phobias; see Table 129-1) are among the most common mental health disorders in children and adolescents. Anxiety disorders often occur concomitantly with chronic medical conditions—affecting children's use of medical resources through frequent emergency department visits and hospitalizations—and with other psychiatric disorders, especially depression. Anxious children often have an anxious or a depressed parent.

The guidance in this chapter applies to the care of children presenting with symptoms of anxiety in pediatric clinical settings. Though, as noted above, there are several distinct forms of anxiety disorders, they often co-occur, sharing core symptoms and approaches to initial treatment. Thus the pediatrician may want to start building competence in this area by learning about anxiety problems in general before trying to further differentiate the various disorders.

The following guidance is based on the work of the World Health Organization, whose recommendations may be updated annually. The most up-to-date information can be found at [www.who.int](http://www.who.int).

### FINDINGS SUGGESTING ANXIETY

Symptoms of anxiety vary by age. Children may experience developmentally normal fears; they may have fears that are exaggerated or persistent beyond norms for their age; and they may have fears and associated reactions or panic attacks that impair their functioning at school, at home, or with peers. Box 129-1 provides a summary of the symptoms and clinical findings that suggest anxiety. These may be elicited from either parents or youth. Parents and youth often disagree on the severity of anxiety symptoms; however, agreement is much better if the discussion is about whether there are symptoms at all, regardless of severity or effect on function. Agreement at this level may facilitate further discussion of how to approach the problem.

**Table 129-1** General Overview of Anxiety and Anxiety-Related Disorders

TYPE	DESCRIPTION
<b>ANXIETY</b>	
Generalized anxiety disorder	Excessive anxiety and worry about a number of events or activities. Children tend to worry excessively about their competence or the quality of their performance at school or in sporting events.
Panic disorder	Recurrent, unexpected, abrupt surge of intense fear or discomfort that reaches a peak within minutes and includes symptoms such as sweating, trembling, palpitations, and dizziness.
Separation anxiety disorder	Developmentally inappropriate and excessive fear or anxiety concerning separation from those to whom the individual is attached.
Agoraphobia	Marked fear or anxiety in using public transportation, being in open or enclosed spaces, standing in line or being in a crowd, or being outside of the home alone.
Social phobia	Marked fear or anxiety about 1 or more social situations in which the individual is exposed to possible scrutiny by others. In children, the anxiety must occur in peer settings and not just during interactions with adults.
Specific phobias	Marked fear or anxiety about a specific object or situation (eg, insects, heights, storms, needles, airplanes, loud sounds, costumed characters). In children, the fear or anxiety may be expressed by crying, tantrums, freezing, or clinging.
<b>OBSESSIVE-COMPULSIVE DISORDERS</b>	
Obsessive-compulsive disorder (OCD)	Presence of obsessions or compulsions. Obsessions are recurrent and persistent thoughts, urges, or images that are experienced as intrusive and unwanted. Compulsions are repetitive behaviors or mental acts that an individual is driven to perform, often in response to an obsession or rigidly applied rules.
<b>TRAUMA- AND STRESSOR-RELATED DISORDERS</b>	
Post-traumatic stress disorder (PTSD)	Development of characteristic symptoms following exposure to actual or threatened death, serious injury, or sexual violence.

Derived from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Arlington, VA: American Psychiatric Association; 2013.

**BOX 129-1 Symptoms and Clinical Findings Suggesting Anxiety**

- Normal fears (eg, strangers, dark, separation, new social situations, unfamiliar animals or objects, public speaking) are exaggerated or persistent.
- Fears are keeping child from developmentally appropriate experiences (eg, school refusal, extreme shyness or clinging, refusal to sleep alone).
- Tantrum, tearfulness, acting-out behavior, or another display of distress occurs when child is asked to engage in feared activity.
- Child worries about harm coming to self or loved ones or fears something bad is going to happen.
- Behavior changes following a traumatic experience, such as abuse, witness to violence, loss of a loved one, or medical trauma, as follows:
  - **Infants and toddlers:** Crying, clinging, change in sleep or eating habits, regression to earlier behavior (eg, bed-wetting, thumb-sucking), repetitive play or talk
  - **3- to 5-year-olds:** Separation fears, clinging, tantrums, fighting, crying, withdrawal, regression to earlier behavior (eg, bed-wetting, thumb-sucking), sleep difficulty
  - **6- to 9-year-olds:** Anger, fighting, bullying, irritability, fluctuating moods, fear of separation or of being alone, fear that traumatic events will recur, withdrawal, regression to earlier behavior, physical complaints (eg, stomachaches, headaches), school problems (eg, avoidance, academic difficulty, difficulty concentrating)
- **10- to 12-year-olds:** Crying, aggression, irritability, bullying, resentment, sadness, social withdrawal, fears that traumatic events will recur, suppressed emotions or avoidance of situations or discussions that evoke memories of the traumatic event, sleep disturbance, concern about physical health of self or others, academic problems or decline related to lack of attention
- **13- to 18-year-olds:** Numbing, reexperiencing, avoidance of feelings (or situations or discussions that evoke memories of the traumatic event), resentment, loss of trust or optimism about future, depression, withdrawal, mood swings, irritability, anxiety, anger, exaggerated euphoria, acting out, substance use, fear of similar events, appetite and sleep changes, physical complaints, academic decline, school refusal
- Somatic features accompany worries: palpitations, stomachaches, headaches, breathlessness, difficulty getting to sleep, nausea, feeling wobbly (“jelly legs”), butterflies.
- *Panic attacks* occur in response to feared objects or situations, or happen spontaneously. These are unexpected and repeated periods of intense fear, dread, or discomfort along with symptoms such as racing heart-beat, shortness of breath, dizziness, light-headedness, feeling smothered, trembling, sense of unreality, or fear of dying, losing control, or losing one’s mind. Panic attacks often develop without warning and last minutes to hours.

**TOOLS TO ASSIST WITH IDENTIFICATION**

Because many children do not spontaneously disclose their symptoms, standardized psychosocial screening instruments may be used to identify children with symptoms of anxiety. Several instruments have versions to collect information directly from the youth or from parents or teachers. Table 129-2 provides an overview of general psychosocial screening tools available in the public domain, along with results suggesting that anxiety may be present. Use of additional instruments, such as the Spence Children’s Anxiety Scale or Screen for Child Anxiety Related Disorders 2 (SCARED), can help to confirm findings of the initial screening; and use of a functional assessment tool, such as the Strengths & Difficulties Questionnaires (SDQ) or Columbia Impairment Scale (CIS), will assist in determining whether the child is significantly impaired by the symptoms. Use of a tool to assess the effect of the child’s problem on other members of the family may also be helpful; the Caregiver Strain Questionnaire (CGSQ) is an example.

It is important to differentiate the use of these tools as screening instruments at routine visits from their use to refine concerns that have already been raised. When used as screening tools, they tend to have relatively low sensitivity and positive predictive value.

That is, positive results need further discussion to understand the meaning of the result, and negative results may not be reassuring if the parent or youth are truly concerned. When used to follow up on existing concerns, results still need discussion with families, but are more likely to be a fair indicator of the nature and severity of the child’s problems.

**ASSESSMENT**

Assessment begins by differentiating the child’s symptoms from normal behavior. Some children have a temperament that is, from the outset, marked by having more difficulty with change and wariness of new situations or individuals. Recognizing that these are longstanding traits can help parents promote active coping skills and avoid misinterpreting the child’s behavior as oppositional. Anxiety is a universal experience, and it can occur predictably at particular stages of life or in particular situations. When anxiety persists outside of these stages and situations, or when its severity is disruptive, further assessment and treatment may be warranted. Some stages in which particular anxieties may normally emerge include the following:

- **8 to 9 months:** Peak of stranger anxiety.
- **Toddlers and early school age:** Development of separation anxiety (fear of new people, places, or

being away from trusted caregivers), usually ends by age 2 to 3 years. Depending on their temperament, toddlers and young children may have greater or lesser tolerance of changes to routine or expectations or of novel experiences (which can include new clothing, foods). Fears of the dark (or of unseen monsters) are common and exacerbated by other stresses and exposure to frightening media.

- **5 to 8 years:** During this period, many children experience an increase in worry about harm to parents or attachment figures. Worries may be triggered by illness or death in family members, by the child's own illness, or by world events.
- **School-aged children of any age:** Many children experience anxiety and distress at the time of high-stakes testing, as well as initial reluctance to socialize in new situations.
- **Adolescence:** Previously resolved anxiety issues often occur again in early adolescence, sometimes associated with concerns about appearance, new social situations, and school performance.

Children with anxiety disorders have fear and distress that interferes with functioning in response to everyday situations. Verbal older children and adolescents are usually able to describe their fears ("worries" may be a more understandable concept), but evaluating reports of younger children's anxiety may be challenging, especially if the parent giving information is also anxious; therefore, it is important to communicate directly with children about these symptoms and to observe or get the child's report of physiologic symptoms (eg, increased heart rate, shortness of breath, numbness, tingling). Sometimes children will display anxiety through repetitive play that acts out their concerns—crashing toy cars or having violent or tragic things happen to dolls—or through drawings that they make in response to simple requests to "draw something." Bad behavior can also be a masked presentation of anxiety. Children and youth at any age may become irritable or oppositional in the face of situations—imminent or anticipated—that they fear. Depression or bereavement may mimic or co-occur

with anxiety, so at least some exploration of other emotional symptoms and of current stressors is always warranted. When children and youth of any age are anxious, it is always important to ask about stressors in the family environment—serious illness (including anxiety and depression) in a family member, economic problems, or marital discord.

Anxiety, like depression, also may occur in multiple family members. When children are found to be anxious, it is not unusual to find that one or more close family members are anxious as well. Helping parents manage their own anxiety can be very important, especially, as discussed in the following text, when trying to use modelling as a form of treatment. Table 129-3 provides a summary of these conditions.

Children with anxiety sometimes have panic attacks, which are episodes of autonomic arousal that occur suddenly, often (but not always) cued by thoughts of a feared situation. People experiencing panic attacks usually report sudden onset of shortness of breath, palpitations, trembling, diaphoresis, and often a feeling of faintness, dread, or impending doom. The attacks usually subside by themselves over the course of several minutes, but it is not unusual, especially among teenagers, for some of the symptoms to be prolonged and result in a call for emergency medical assistance. Differentiating panic attacks from hypoglycemia, asthma exacerbations, or cardiac conditions may in itself help with their treatment; often they will improve as other aspects of anxiety are treated. As noted in the following text, they can sometimes be suppressed with medication if their frequency is causing disability, which can facilitate treatment of the underlying anxiety problem.

Treatment for anxiety generally involves identifying the specific situations in which it is triggered and helping individuals learn how to reduce anxious feelings when they occur and gradually become tolerant of the triggers to the point where anxious responses are either no longer evoked or remain manageable. Treatment is usually tailored to the specific triggering situation, often through carefully supported increasing

**Table 129-3** Conditions That May Mimic or Co-occur With Anxiety

CONDITION	RATIONAL
Learning problems or disabilities	If symptoms of anxiety are associated with problems of school attendance or performance, the child may be experiencing academic difficulties. (See Chapter 172, Learning Difficulty, for more information.)
Somatic complaints	Anxious children may present with a variety of somatic complaints (eg, gastrointestinal symptoms, headaches, chest pain). These may elicit medical workups if they are not recognized. Conversely, acute or chronic medical conditions or pain syndromes may cause anxiety.
Depression	This can be very difficult to distinguish from anxiety. Depression coexists in half or more of anxious children. Marked sleep disturbance, disturbed appetite, low mood, or tearfulness in the absence of direct anxiety provocation could indicate that a child is depressed.
Bereavement	Most children will experience the death of a family member or friend sometime in their childhood. Other losses may also trigger grief responses—separation or divorce of parents, relocation, change of school, deployment of a parent in military service, breakup with a girlfriend or boyfriend, or remarriage of a parent. Such losses are traumatic. They may result in feelings of insecurity and anxiety immediately following the loss or exacerbate existing anxiety. Furthermore, they may make the child more susceptible to impaired functioning at the time of subsequent losses.
Autism spectrum disorders including pervasive developmental disorder and Asperger syndrome	Children who have these difficulties also have problems with social relatedness (eg, poor eye contact, preference for solitary activities), language (often stilted), and range of interest (persistent and intense interest in a particular activity or subject). They often will have very rigid expectations for routine or parent promises and become anxious or angry if these expectations are not met.
Exposure to adverse childhood experiences (ACE)	Children who have experienced or witnessed trauma, violence, a natural disaster, separation from a parent, parental divorce or separation, parental substance use, neglect, or physical, emotional, or sexual abuse are at high risk of developing emotional difficulties such as adjustment disorder or PTSD. Determination of the temporal relationship between the trauma and onset of anxiety symptoms is essential. Denial of trauma symptoms does not mean trauma did not occur; questions about ACE should be repeated as a trusting relationship is established.
Psychosis	Symptoms associated with psychosis, such as hallucinations or delusions, may occur in children with PTSD. They may also occur infrequently with adolescent onset of bipolar disorder and are features of schizophrenia, which may also have its onset in adolescence. The teen may manifest fear without disclosing the hallucinations or delusions.
Physical illness	Medical issues that can mimic or provoke anxiety symptoms include thyroid disease, hypoglycemia, side effects of medications (eg, bronchodilators), and endocrine tumors (pheochromocytoma). Drug or alcohol withdrawal is a consideration for teens (the latter potentially a medical emergency).
Selective mutism	Consider this if a child who has had normal language development suddenly stops talking in certain situations (most often in school and to adults outside the home). This can be confused with children making a language transition (eg, a child raised speaking Spanish who is suddenly placed in an English-speaking class.)

exposure to the trigger coupled with practice of a variety of cognitive, somatic, and social coping strategies. Treatment of OCD and PTSD involves these same treatment elements, but differs in that the etiology of the disorders takes on a role in treatment (whereas in the treatment of other anxiety disorders there is less emphasis on how the problem began and more on how to get it to remit). For OCD, the fact that obsessions and compulsions develop without particular triggers (though they can be worsened by other stresses) plays an important role in children's and family's understanding of the condition. For PTSD, linking what may be nonspecific symptoms to a particular past trauma can be an important part of treatment.

- **Consider OCD in the presence of marked rituals or compulsive behaviors.** Most children have

phases of ritualized behavior that usually can be distinguished from OCD by the degree of distress caused if a ritual is interrupted. Individuals with OCD usually report—or after discussion will admit—that the symptoms have a major effect on how they plan their activities or interact with others, and that attempts to stop the thoughts or actions have been difficult to carry out or even contemplate. School-aged children and adolescents will often—once the symptoms can be openly discussed—admit being aware that there is something objectively out of proportion about their concerns, even though they remain difficult to resist. The most common concerns center on contamination—fears of touching things that may be dirty, or the need to repetitively wash or bathe. Other common difficulties are the need to check that something has been done (usually

related to security—doors locked, stove turned off) or a need to have one's personal possessions in a particular order or place.

- **Consider PTSD if the onset of anxiety was preceded by an extremely distressing experience**, such as witnessing violence, losing a loved one, undergoing medical trauma, or experiencing sexual or physical abuse. Parents may be unaware of exposures to trauma, such as bullying at school or in the community, and there may be major traumas in the family (eg, serious illness in a parent, pending divorce) that are similarly not discussed or disclosed; consequently, clinicians may need to interview children and parents separately to elicit a complete history. It is important to note that the triggering circumstances need only be traumatic in the eye of the child. Most antecedents have in common situations in which the child felt that there was risk to her life, or that of someone close to her. The 3 hallmark symptoms of anxiety in the wake of trauma are *re-experiencing* (often repetitive play in young children), *avoidance* of memories or situations that recall the trauma, and *hypervigilance* (eg, increased worry about safety, startling or anxiousness at unexpected sounds or events). Avoidance can also take the form of changing the subject or acting inappropriately when subjects related to trauma are brought up in conversation. Children most at risk for developing PTSD following trauma or loss are those with preexisting mental health conditions, those whose caregivers are experiencing emotional difficulties, those facing preexisting or consequent family life stressors, such as divorce or loss of job, those with previous loss or trauma experiences, those repeatedly exposed to media coverage of traumatic events, and those with a limited support network. Clinicians can provide the child with a safe and comfortable environment to express her feelings and allow the child to control the interview, taking breaks or discontinuing as needed. Even children with limited symptoms of PTSD after a trauma can benefit from treatment.

## PLAN OF CARE FOR CHILDREN WITH ANXIETY

The care of a child experiencing anxiety can begin in the primary care setting from the time symptoms are recognized, even if the child's symptoms do not rise to the level of a disorder and regardless of whether referral to a mental health specialist is ultimately part of the care plan. Both children and parents may, by temperament, be more or less socially outgoing and more or less open to new or unexpected experiences. Helping parents appreciate their own areas of comfort and discomfort, and how these may differ from those of their child, can be a first step toward treatment. Regardless of parent or child temperament, parents can be helped to learn ways to help their child gain better emotional regulation.

### Engage Child and Family in Care

Without engagement, most families will not seek or persist in care. The process may require multiple primary care visits.

Reinforce strengths of the child and family (eg, good relationships with at least 1 parent or important adult, prosocial peers, concerned or caring family, help-seeking, connection to positive organizations) as a method of engagement, and identify any barriers to addressing the problem (eg, stigma, family conflict, resistance to treatment). Use "common factors" techniques to build trust and optimism, reach agreement on incremental next steps, develop a plan of care, and collaboratively determine the role of the primary care physician. Regardless of other roles, the primary care physician can encourage a positive view of treatment on the part of the child and family.

Remember that it is in many ways normal for people with anxiety problems to initially resist their treatment. This is because most people cope with anxiety through avoidance, and initiating treatment means that one has to start thinking about the situations that trigger the anxious feelings.

### Provide Psychoeducation

Tell the family a little bit about anxiety; much of the material discussed previously in this chapter could be useful. Emphasize that anxiety is a normal human emotion, that anxiety problems are very common, and that they can be addressed. For some children and families, it can be helpful to talk about variations in temperament or personal style that make some people more or less anxious in new situations or more or less responsive to threats. Again, acknowledge that these are traits we are born with and not to be ashamed of. The clinician can also say that anxiety has nothing to do with bravery or accomplishment, noting that many famous performers and athletes experience serious degrees of "stage fright" and yet, with support and encouragement, have become very successful (usually by working hard to prepare themselves). It can be helpful to point out that one can very much enjoy and be good at things but still experience anxiety when having to do them in front of others or in particularly high-stakes circumstances.

### Encourage Healthy Habits

Encourage exercise, outdoor play, balanced and consistent diet, sleep (critically important to mental health), special time with parents, frequent acknowledgment of the child's strengths, and open communication with a trusted adult about worries. Children, particularly younger ones, should be shielded from certain types of media, such as the news, when there are violent or disturbing images or stories. Likewise, TV shows, even some cartoons, may contribute to a child's feeling anxious. For preteens and teens, media messages about body image and social media may contribute to or exacerbate anxiety.

### Reduce Stress

Consider the child's social environment (eg, family social history, parental depression screening, results of any family assessment tools administered, reports from child care or school). Questions to raise might include the following:

- *Is an external problem causing the child to be anxious* (eg, bullying at school, academic difficulties,

disruption at home)? Take steps to address the problem.

- *Is the child exposed to frightening electronic media?* Sometimes this results from unsupervised access to television or Internet content, but it may also occur during shared family activities (eg, movies, TV, video games) when parents or other family members underestimate or fail to recognize how frightened the child has become. Limiting these exposures, and providing reassuring explanations if they occur, can be an important part of reducing anxiety, especially among younger children.
- *Is the child's worry about a parent's welfare legitimate because of a serious illness, domestic violence, or parent impairment?* Address environmental issues, enlisting the help of school personnel or social services as appropriate to the situation.
- *Is the parent anxious or depressed or impaired because of substance abuse? Has the parent experienced trauma or loss?* Anxious children very often have an anxious or a depressed parent. Advise parents to minimize their own displays of fear or worry when the child is present. A referral to adult mental health services might also be appropriate.

### Offer Initial Intervention(s) to Address the Anxiety Symptoms

The strategies described in the following text are common elements of evidence-based psychosocial interventions for anxiety disorders. They are applicable to the care of children with mild or emerging anxiety symptoms and to those with impairing symptoms that do not rise to the level of a disorder. They can also be used as initial primary care management of children with anxiety disorders and while readying children for referral or awaiting access to specialty care. Medications can be helpful, especially to speed suppression of panic and OCD symptoms or when very time-limited and severe stressors need to be faced, but, in the absence of psychosocial treatments, symptoms may recur as the medications are discontinued. Interpreting the results of a medication trial can also be problematic, because the severity of anxiety problems is often cyclic. Families may seek care as symptoms are peaking. If medication is started at this point, it often cannot be determined if the condition improved on its own or responded to medication. Thus, starting with a carefully administered psychosocial treatment plan may be a reasonable first step until the severity and natural history of the anxiety concerns are better understood.

*Guide parents in managing the child's fears.* Help the parents to identify their child's fear(s) and reach consensus with the child and family on the goal of reducing symptoms and on a way to do it. This could include teaching the child and parent cognitive behavioral strategies to improve coping skills at times when the child feels anxious. Examples of these skills include deep breathing, muscle relaxation, positive self-talk, thought stopping, and thinking of a safe place. The child and family may also benefit from reading

material or a Web course, as appropriate to their literacy level.

*Gradually increase exposure.* One of the best validated approaches to anxiety and phobias is to gradually increase the child's exposure to feared objects or experiences. The eventual goal is to master rather than avoid feared things. To do this, the parent might start out with brief exposure to the feared object or activity and gradually lengthen the exposure. First, help the child imagine or talk about the feared object or activity or look at pictures; then learn to tolerate a short exposure with support from the parent; proceed to tolerate a longer exposure in a group or with the parent or another coach; and, finally, tolerate the feared activity alone (when that is appropriate) but with a chance to get help if needed. During these trials, parents need to stay as calm and confident as possible; if they become distressed, it will be a cue for the child to become distressed.

*Manage school phobia.* For some children who are vulnerable to anxiety, it is necessary to return the child promptly to the anxiety-producing situation. School phobia is an example. For the child who is afraid at school or resists going to school, rule out bullying, trauma, learning difficulties, and medical conditions that may be contributing to stress and fear. Also, the primary care physician can partner with school personnel to manage the child's return to school and gently, but firmly, insist that the child attend school, in addition to providing positive feedback and calm support. If absence becomes prolonged or parents are reluctant to support the child's return, referral to a mental health specialist will be necessary.

If anxiety is secondary to environmental stress, support the parents' efforts to protect the child, buffer stress, and help the child master his anxiety. Help the child to rename the fear (ie, "annoying worry") and assist the child to become the boss of the worry. It is also helpful to reward brave behavior (see Table 129-4).

**Table 129-4**

### Tips for Reward System

#### REWARD SYSTEMS FOR BRAVE BEHAVIOR

#### GUIDELINES FOR USE

Small rewards  
Star charts

- Include positive feedback.
- Focus on only 1 or 2 behaviors at a time.
- Have 1 star chart per behavior.
- Negotiate rules for the star chart (eg, sleeping in own bed for 1 night = 1 star; 4 stars = trip to the pool).
- Ignore mistakes and failures; do not even mark them on the star chart.
- Continue awarding stars when they are earned.

*Attend to overall parenting style.* Children can become anxious if parents are inconsistent about rules and expectations. Determine whether there are catastrophic consequences for failure (“I know Dad will get angry if I bring home a bad grade....”). Explore the child’s sense of responsibility for the family’s stresses (“I know that the only reason Mom and Dad work hard is so I can go to a better school, so I’m afraid that if don’t do well....”).

*Treat panic attacks.* Early treatment, including psychosocial and psychopharmacologic therapy, is useful and may prevent progression to agoraphobia and other problems such as depression and substance abuse. When children are aware of the triggers for their attacks, developing alternative responses to those triggers can diminish the frequency of attacks. When attacks appear without apparent triggers, referral for pharmacologic treatment may be most effective.

Links for further information regarding the treatment of anxiety symptoms are provided in Tools for Practice at the end of this chapter.

### Provide Resources

Helpful handouts and publications are included in Tools for Practice: Engaging Patient and Family at the end of this chapter. Provide the family with contact numbers and resources in case of emergency.

### Monitor the Child’s Progress Toward Therapeutic Goals

Child care, preschool, or school reports can be helpful in monitoring progress. Screening instruments that gather information from multiple reporters (youth, parent, teacher), such as the SDQ, can be helpful in monitoring progress with symptoms and functioning.

It is important for the primary care physician to work with the family to understand that it is not uncommon for treatment to be successful for a period of time and then seem to lose effectiveness. This can happen when there are new stresses or demands, or when, after a period of success, there has been a letup on treatment. If troubleshooting existing treatment and ways of dealing with new stresses does not help get function back to baseline, new treatments or new diagnoses need to be considered. In particular, as school demands increase, learning issues may need to be considered even if they were not seen as contributing problems in the past.

### Involve Specialist(s)

Involve specialist(s) if the child does not respond to initial interventions or if the following clinical circumstances exist:

- Child has severe functional impairments at school, at home, or with peers—for example, if anxiety threatens to interfere with academic progress or other developmentally important goals.
- Multiple symptoms of anxiety occur in many domains of life (eg, fearful of new situations, reluctant to do things in public, trouble separating, worries a lot).

- The child or parent is very distressed by the symptom(s).
- There are co-occurring behavior problems. (The combination of shyness, anxiety, and behavior problems is thought to be particularly risky for future behavior problems of a more serious nature.)
- The anxiety was preceded by serious trauma or symptoms suggesting PTSD.
- The child seems to have panic disorder or OCD, both of which require specialized treatment.
- The anxiety occurs in a child with an autism spectrum disorder. Anxiety about both normal childhood issues (weather, animals), as well as the orderliness and predictability of daily routines, is relatively common among higher functioning children who display autism spectrum symptoms, including stereotyped interests and poor social perceptions and skills.

*When specialty care is needed, ensure that it is evidence-informed and assist the family in accessing it.* A variety of evidence-based and evidence-informed psychosocial interventions, and some pharmacologic interventions, are available for the treatment of anxiety disorders in children and adolescents. Ideally, those referred for care in the mental health specialty system would have access to the safest and most effective treatments. Table 129-5 provides a summary of these interventions. Youth referred for mental health specialty care complete the referral process only 61% of the time, and a significantly smaller number persist in care. Approaches to improving the referral process include making sure that the family is ready for this step in care, has some idea of what the specialty care will involve, and understands what the primary care physician’s ongoing role may be. If the specialty appointment is not likely to occur shortly, the physician can work with them on a plan to manage the problem as well as possible in the meantime.

Note that not all evidence-based interventions may be available in every community. If a particular intervention is not available, this becomes an opportunity to collaborate with others in the community to advocate on behalf of children. Increasingly, states offer both telepsychiatry services and consultation/referral support “warmlines” that help physicians provide initial treatment and locate resources. The availability of the latter form of help is tracked at [www.nncpap.org](http://www.nncpap.org).

*Reach agreement on respective roles in the child’s care.* If the child is referred to mental health specialty care for an anxiety disorder, the physician may be responsible for initiating medication or adjusting doses; monitoring response to treatment; monitoring adverse effects; engaging and encouraging the child and family’s positive view of treatment; and coordinating care provided by parents, school, medical home, and specialists. In fact, the child may improve just knowing that the physician is involved and interested. Resources available to help clinicians in these roles are provided in Tools for Practice: Medical Decision Support.

## Chapter 130

# ATAXIA

Philip Overby, MD

Ataxia derives from the Greek—*a* (without), *taxia* (order) and means a “lack of order.” Broadly, ataxia encompasses disorders in which there is an absence of coordinated movements, often involving gait. Although ataxia can certainly be chronic, as a presenting symptom in pediatrics it is almost always acute. For the treating physician, the list of its potential causes can be daunting (see Box 130-1), in part because ataxia can be caused by dysfunction at any level of the motor system from brain to muscle. Diagnostically, the goal is to localize the ataxia to the level of dysfunction.

## EVALUATION

### History

Practically, the initial approach to the child with acute ataxia should focus on the serious causes of ataxia. Once these have been excluded clinically, more common as well as treatable causes can be considered. Life-threatening conditions fall into 4 broad categories: infection or inflammation, neoplasm, stroke, and ingestion. Although the initial history should be

directed foremost at identifying serious causes of acute ataxia, in most cases, the causes of acute ataxia are self-limited and benign. One retrospective study of 40 pediatric cases found that 80% could be attributed to acute cerebellitis, toxic ingestion, and Guillain-Barré syndrome (GBS). Note that although it certainly is a common cause of acute ataxia in children, ingestion in this discussion is included among the more serious causes because missing the diagnosis can be life threatening.

The history should explore evidence of recent or current infection: fever, rash, respiratory symptoms, or vomiting. Questions about possible toxic exposures in the home, such as medications, alcohol, or illicit drugs, are essential. The possibility of trauma, observed or unobserved, should be explored with all caregivers and children who might be aware of it.

Associated symptoms can further guide the history. Although acute cerebellitis is characterized by preservation of alertness, a change in mental status is concerning and can signal a systemic process. Considerations include toxic ingestion, infection, or mechanical compression of the brainstem by a tumor or abscess. Headaches, recurrent vomiting, visual loss or diplopia, and worsening of symptoms when supine can be signs of elevated intracranial pressure (ICP) from hydrocephalus in the setting of posterior fossa masses. It should be noted, however, that these findings can be late or even intermittent, and their absence does not exclude elevated ICP.

### BOX 130-1 Causes of Acute Ataxia in Childhood

#### INFECTIOUS/IMMUNE-MEDIATED CEREBELLAR DISORDERS

- Acute cerebellar ataxia<sup>a</sup>
- Acute demyelinating encephalomyelitis<sup>a</sup>
- Systemic infections
- Brainstem encephalitis
- Multiple sclerosis

#### MASS LESIONS

- Tumors
- Vascular lesions
- Abscesses

#### HYDROCEPHALUS

#### TRAUMA

- Cerebellar contusion or hemorrhage
- Posterior fossa hematoma
- Postconcussion syndrome
- Vertebrobasilar dissection

#### STROKE

- Vertebrobasilar dissection or thromboembolism
- Cerebellar hemorrhage

#### PARANEOPLASTIC DISORDERS

- Opsoclonus-myoclonus syndrome

#### SENSORY ATAXIA

- Guillain-Barré syndrome
- Miller-Fisher syndrome

#### PARETIC ATAXIA

- Upper motoneuron
- Lesions of frontal lobe, corticospinal pathways
- Lower motoneuron
- Spinal cord: transverse myelitis, vascular lesions, cord compression
- Peripheral nerve: Guillain-Barré syndrome, Miller Fisher syndrome, tick paralysis

#### OTHER NEUROLOGIC DISORDERS

- Inborn errors of metabolism (see Box 130-2)<sup>a</sup>
- Basilar migraine, benign paroxysmal vertigo
- Nonconvulsive seizures
- Central pontine myelinolysis
- Wernicke encephalopathy

#### FUNCTIONAL ATAXIA

<sup>a</sup>Most common.

From Ryan MM, Engle EC. Topical review: acute ataxia in childhood. *J Child Neurol.* 2003;18:309–316, with permission from SAGE Publications.

Recent and abrupt onset of symptoms is more suggestive of a vascular, toxic, or infectious cause. Tumors and immune-mediated processes are typically more subacute in their progression. The exception is tumors that hemorrhage. If a patient with a known brain tumor has an acute change in mental status, or acute ataxia, he or she should be evaluated for hemorrhage acutely with a head CT. If hemorrhage is present, neurosurgery should be contacted immediately. Prior similar episodes are suggestive of chronic conditions such as migraine, or even seizures. Recurrent episodes are also potentially suggestive of metabolic processes (see Box 130-2).

### Physical Examination

Life-threatening causes of acute ataxia typically originate in the central nervous system. They tend to involve the posterior fossa or brainstem. In particular, symptoms are referable to 3 sources: cranial nerves, the pyramidal tracts, and the cerebellum. Moreover, the involvement of brainstem and cerebellar structures typically results in abnormalities both on history and physical examination. As such, a normal neurologic examination, carefully performed, is a pertinent negative.

The physical examination begins with vital signs. Fever suggests infection. Autonomic changes can be seen in the setting of acute stroke, elevated ICP, or peripheral processes such as GBS. The examination can be challenging because the child may be uncooperative. Given this, the examination should move from the

least to the most invasive. General observations (Does the child appear ill or uncomfortable? Is she agitated or careful not to move?) are valuable. The somatic examination should explore for evidence of meningismus: neck stiffness as well as photophobia and discomfort with movement. Next, attention should be given to the child's mental status. Behavioral changes, decreased alertness, inattention, or dysarthria can all be clues to elevated ICP, brainstem compression, or cranial neuropathies that may affect eye movements. If possible, fundi should be inspected for papilledema. The presence or absence of associated findings to suggest elevated ICP, such as restriction of upward gaze or lateral eye movements, should also be noted.

Cerebellar hemisphere dysfunction is often associated with a wide-based gait. Attempts to stand with feet close together can result in swaying from side to side with eyes open or closed. Unilateral weakness or pyramidal tract dysfunction manifests as asymmetries in arm or leg use. Subtle gait difficulties can be elicited with tandem walking. Sensory ataxia can be elicited by asking the child to stand still with feet together and eyes closed, the "Romberg test," which examines the dorsal columns. A positive test is one in which swaying or a frank fall occurs.

### Differential Diagnosis—Serious Disorders

#### Acute Stroke

In the absence of trauma, hemorrhagic stroke (intracerebral hemorrhage, or ICH) in children most commonly

### BOX 130-2 Causes of Episodic or Intermittent Ataxia in Childhood

#### RECURRENCE OF ACUTE CEREBELLAR ATAXIA<sup>a</sup>

##### MIGRAINE OR MIGRAINE EQUIVALENTS

- Basilar migraine<sup>a</sup>
- Benign paroxysmal vertigo
- Benign paroxysmal torticollis of infancy
- Alternating hemiplegia of childhood

##### METABOLIC DISORDERS

- Mitochondrial disorders
  - Pyruvate decarboxylase deficiency
  - Pyruvate dehydrogenase deficiency
  - Leigh disease
- Amino acidopathies
  - Maple syrup urine disease, intermittent form
  - Hartnup disease
  - $\gamma$ -Glutamylcysteine synthetase deficiency
- Urea cycle disorders
  - Carbamoyl phosphate synthetase type 1 deficiency
  - Ornithine transcarbamylase deficiency
  - Citrullinemia
  - Arginosuccinic aciduria

- Organic acidopathies
  - Holocarboxylase deficiency
  - Biotinidase deficiency
  - Isovaleric acidemia
- Carnitine acetyltransferase deficiency

##### RECURRENT GENETIC ATAXIAS

- Episodic ataxia type 1 (paroxysmal ataxia with myokymia)
- Episodic ataxia type 2 (acetazolamide responsive)
- Episodic ataxia types 3 and 4
- Episodic ataxia with paroxysmal dystonia
- CAPOS syndrome (cerebellar ataxia, areflexia, pes cavus, optic atrophy, sensorineural hearing loss)

##### NONCONVULSIVE SEIZURES

##### DRUG INGESTION<sup>a</sup>

##### PAROXYSMAL TONIC UPGAZE OF CHILDHOOD

##### COGAN SYNDROME

<sup>a</sup>Most common.

From Ryan MM, Engle EC. Topical review: acute ataxia in childhood. *J Child Neurol*. 2003;18:309–316, with permission from SAGE Publications.

results from an arteriovenous malformation (AVM). Emergent neurologic and neurosurgical evaluation is critical. Associated symptoms of ICH include headache, seizure, or visual loss. Decompression of a posterior fossa hemorrhage can be life saving. Hemorrhagic stroke will be apparent on head computed tomography. Ischemic stroke of the posterior circulation is rare in children but can be seen in the setting of vertebral dissection—often from trauma.

### **Acute Disseminated Encephalomyelitis**

Acute disseminated encephalomyelitis (ADEM) is an acute demyelinating event that is typically most severe at onset. It is an immune-mediated encephalitis often occurring in the context of viral or postviral infections. The white matter of the brain and spinal cord are preferentially affected. Typically, ADEM follows a prodrome of fever, vomiting, headache, and malaise. The neurologic features are broad: unilateral or bilateral pyramidal signs (60%–95%), acute hemiplegia (76%), ataxia (18%–65%), cranial nerve palsies (22%–45%), visual loss from optic neuritis (7%–23%), seizures (13%–35%), and spinal cord involvement (24%). Ultimate outcome does not seem to be affected by immunologic therapy, which can, however, hasten recovery.

### **Tumor**

Childhood brain tumors occur most frequently in the posterior fossa. The most common tumors are medulloblastoma, brainstem glioma, ependymoma, and cystic astrocytoma. There are 3 potential areas of involvement: cranial nerves, pyramidal tracts, and the cerebellum. Although symptoms may be reported to have developed over the course of days, a careful history typically reveals subtle signs of weakness and coordination difficulties lasting weeks to months. Signs from obstruction of cerebrospinal fluid (CSF) flow are common, and children younger than 2 years typically present with increasing head circumference. In older children, symptoms such as headaches and ataxia are more common. The average time from symptom onset to diagnosis is 7 months. Although less common than brain tumors, spinal tumors can also present with ataxia. Depending on the spinal level, signs of weakness or sensory loss referable to the lower or upper extremities with preservation of reflexes will be present. In addition, paraneoplastic presentation of tumors (eg, opsoclonus-myoclonus syndrome) at times need to be considered in the differential diagnosis of ataxia.

### **Cerebellitis**

Acute cerebellitis, also known as acute cerebellar ataxia, is a common, typically benign infectious or parainfectious phenomenon. It typically occurs in preschool- and school-aged children. Generally, the acute ataxia is most prominent on awakening and improves over the course of hours to days. Rarely, however, fulminant cerebellitis occurs. Unlike its more benign form, fulminant cerebellitis progresses from its onset to the development of encephalopathy, with

hydrocephalus caused by obstruction of the fourth ventricle. Outcomes can be favorable with aggressive management.

### **Trauma**

Life-threatening conditions to consider in the setting of trauma are hemorrhagic stroke and ischemic stroke from vertebrobasilar artery dissection. In the absence of more diffuse injury causing associated encephalopathy, it is unusual for trauma to present with isolated ataxia. The important exception to this rule is vertebral artery dissection, which represents 7% to 20% of pediatric ischemic strokes. The vertebral arteries supply the posterior circulation. Presenting signs and symptoms are referable to the posterior fossa: ataxia, vertigo, vomiting, diplopia, and head and neck pain. Although these symptoms are common and nonspecific, 88% of patients in a 2005 review had focal neurologic deficits. Fifty percent of children in the same study had a history of trauma.

### **Toxic Ingestion**

Ingestion of a toxin represents a major cause of ataxia in children, accounting for up to 32.5% of cases. Ingestion associated with ataxia includes antihistamines, alcohol, anticonvulsants (especially phenytoin and carbamazepine), piperazine, diphenylhydantoin, barbiturates, carbon monoxide, organic solvents, and bromides. Accidental ingestion occurs in young children. Adolescents can also present after ingestion in attempts to self-harm. Symptoms of ingestion can be nonspecific. Indeed, when symptoms do not fit well into a clinical syndrome, ingestion should become a concern. When considering toxic ingestion, it is also important to evaluate for other evidence of metabolic aberrations, such as hypoglycemia, hyponatremia, and hyperammonemia.

### **Common Causes of Ataxia**

#### **Sensory or Motor Ataxia Caused by Guillain-Barré Syndrome**

Studies of the incidence of GBS in children younger than 16 years old, most of which have been performed in Europe and North America, suggest rates between 0.4 and 1.4 per 100,000. Although the typical presentation of symmetrical weakness is well known, an acute progressive ataxia is another presentation of GBS seen particularly in young children. Important early clues include distal paresthesias or numbness. Younger children may present with prominent symptoms of leg pain, agitation, or vomiting, and meningeal signs may be present on examination. Reflexes are depressed or absent. Lumbar puncture typically demonstrates dissociation between cells and protein, with elevated protein and borderline-to-normal WBC counts. The CSF may be normal on initial presentation.

Three disorders need to be considered in the setting of suspected GBS. First, transverse myelitis (TM) can also present with limb weakness, back pain, and depressed reflexes. Sustained sphincter dysfunction and

a sensory level distinguish TM from GBS. Second, tick paralysis can also present with pure motor weakness and absent reflexes. Particularly in the late spring or summer if careful inspection reveals a tick, its removal is typically curative. Oculomotor paralysis can be a clue and can appear similar to the Miller Fisher variant of GBS, characterized by ataxia, oculomotor palsies, and absent deep tendon reflexes. Finally, brainstem encephalitis can also mimic the Miller Fisher variant of GBS.

### **Acute Cerebellar Ataxia**

Acute cerebellar ataxia (ACA) occurs most commonly in children younger than 5 years old but can occur at any age. It has been associated with a variety of infections but is usually the result of postinfectious demyelination rather than direct infection. The presentation is characterized by maximal deficits at onset, and often on awakening. Pancerebellar dysfunction can result in truncal ataxia, with the consequent inability to sit or stand without assistance. Head titubation, nystagmus, and dysmetria are sometimes present. Mental status is normal. Full recovery is typical but can take as long as 3 to 6 months. There is no evidence that immune therapy such as steroids alters the outcome of ACA.

### **Migraine**

Vertigo as the primary or sole manifestation of migraine occurs with very young children and teenaged girls. Children younger than 4 years can have the abrupt onset of unsteadiness lasting seconds to minutes. More commonly, adolescents describe repeated bouts of isolated vertigo, or headache and vertigo. In both cases, there is usually a family history of migraine and a propensity to motion sickness in the context of a normal neurologic examination.

### **Labyrinthitis**

The clinical symptoms of labyrinthitis are superficially similar to ACA: acute onset of ataxia and nystagmus. However, children with acute labyrinthitis generally appear more ill, have prominent vomiting, and hold themselves still to minimize exacerbation of symptoms. This condition frequently occurs in clusters of exposed individuals, most frequently in spring and early summer, supporting an infectious (likely viral) cause. In particular, the vestibular nerve is inflamed.

### **Laboratory Evaluation**

A thorough history and physical examination often make laboratory testing unnecessary. At a minimum, however, urine toxicology should be considered. If there is a high clinical suspicion, blood and urine samples should be held with the intention of sending targeted analysis following consultation with poison control.

Lumbar puncture should be considered in the setting of suspected infectious or inflammatory processes. Normal white blood cell count or a mild pleocytosis is typical in ACA. More significant pleocytosis or low glucose raises the concern for bacterial meningitis or

encephalitis, and an expanded evaluation for viral (especially herpes simplex virus) and bacterial causes is warranted.

### **Imaging**

Imaging of the brain is indicated in the presence of a focal neurologic examination, or with the inability to perform a reliable neurologic examination in the presence of illness or sedation. Imaging in the absence of these indications is low yield. Acutely, head CT is effective for evaluating for hemorrhage or hydrocephalus. However, magnetic resonance imaging of the brain both spares the child radiation and provides more sensitive visualization of the brain parenchyma. Additional studies with contrast are indicated if there is concern for infection and inflammation or tumor. Imaging of the vasculature with magnetic resonance angiography or magnetic resonance venography is useful when stroke is a consideration. Neurologic consultation should typically be obtained before ordering imaging to optimize the study, and before considering conventional cerebral angiography or computed tomographic angiography.

## **MANAGEMENT**

### **Treatment Approach**

Treatment is directed at the underlying diagnosis. Initial attention to vital signs in the ill child is crucial. Posterior fossa hemorrhage requires urgent neurosurgical consultation. Ischemic stroke requires neurologic consultation and admission to a pediatric critical care unit for further management. In the case of ADEM, immune modulating therapy such as steroids, intravenous immunoglobulin (IVIG), or plasma exchange (PLEX) can be considered: treatment can hasten recovery, but does not appear to alter ultimate outcome. A 2004 study of vestibular neuritis in adults found that vestibular function was improved in patients treated with methylprednisolone but not valacyclovir.

Infectious processes, such as cerebellar abscess or brainstem encephalitis, are treated initially with broad antimicrobial therapy (including ampicillin for *Listeria* in the case of brainstem encephalitis) as well as antiviral therapy (acyclovir for herpes simplex virus) until the causative agent is identified. Brain tumors require neurologic, oncologic, and neurosurgical consultation.

GBS requires admission for monitoring of vital signs and respiratory function. Respiratory function can worsen from presentation, and initial monitoring in the PICU for 24 to 48 hours should be considered. Treatment with IVIG or PLEX speeds recovery, and IVIG is favored because it is less invasive. IVIG should not be used in patients who are immunoglobulin A deficient.

### **Ongoing Care**

Long-term treatment is not typically required for the common causes of pediatric acute ataxia. However, follow-up 2 to 4 weeks after discharge to monitor recovery is reasonable. Prognosis and management

are linked to diagnosis. If persistent or permanent dysfunction results, physical therapy and adaptive devices should be coordinated. Aside from ingestion, few of the causes of ataxia are preventable. In most cases, the outcome is a good one. In patients requiring admission, early recognition leading to early admission and treatment may improve outcomes.

## Chapter 131 BACK PAIN

Joel S. Brenner, MD, MPH; David V. Smith, MD

### DEFINITION

The back encompasses the region from the upper thoracic vertebra (T1) and shoulder girdle to the sacrum and surrounding musculature. The patient who complains of pain in this region may have difficulty localizing the source of the pain and describe it simply as deep pain, or the patient may localize pain to a specific muscle group or vertebral body. Allowing patients to define in their own words the nature, location, and duration of the pain is an important first step in arriving at a clinical diagnosis. If parents, coaches, or peers are available during the interview, they can be valuable to confirm or elaborate on the patient's symptoms. One should keep in mind that young children and adolescents may minimize pain out of imagined fears of diagnostic or therapeutic procedures. Functional disability such as interference with sports, play,

or school may prompt more urgent diagnostic evaluation and treatment.

### EPIDEMIOLOGY

Population-based data on back pain in children are limited, and estimates of prevalence vary considerably depending on sample size and method used. At the least, most studies have consistently shown that the prevalence of back pain increases with age. In nonclinical populations, the prevalence is less than 10% in preteens, progressing to nearly 50% of 18- to 20-year-olds reporting at least one episode of low-back pain. Clearly, most people who experience such pain do not seek medical care. In preadolescent children, back pain is not only unusual but also likely to indicate serious underlying illness when severe or persistent enough to prompt a medical visit. One 6-year study in a tertiary orthopedic setting found that back pain constituted fewer than 2% of referrals in children ages 15 years or younger, but that roughly 50% of these children had serious underlying diseases. From early adolescence onward, back pain becomes more common as a presenting complaint but is more likely to be a benign condition related to acute injury or repetitive stress. The physician presented with a child or adolescent complaining of back pain should use a careful history and physical examination to guide any further laboratory or radiologic evaluation. Overall, they should be aware of the relatively higher risk for serious underlying disease in younger children, even without specific physical findings.

### DIFFERENTIAL DIAGNOSIS

#### Infants

From infancy through the third or fourth year of life, the patient is not capable of localizing or complaining of pain in the back. Unexplained fever or toxicity, along with refusal to walk or stand, may be the presenting signs of diskitis. Other pathologies localized to the back to consider include leukemia, lymphoma, pyelonephritis, vaso-occlusive crisis, or vertebral osteomyelitis in a child who has sickle cell disease, or accidental or nonaccidental trauma.

#### Children

As children mature and become more capable of communicating and localizing symptoms, a specific history of the duration, quality, associated symptoms, and radiation of back pain becomes possible. Back pain before adolescence remains an uncommon presenting complaint and should prompt thorough evaluation. Only after a thorough diagnostic evaluation should the physician consider the diagnosis of muscular or ligamentous strain as a cause of back pain in younger children. The differential diagnosis of back pain in this age group is broad and includes acute leukemia, lymphoma, and primary vertebral tumors, such as Ewing sarcoma, aneurysmal bone cyst, benign osteoblastoma, and osteoid osteomas. Other etiologies include diskitis, an unusual if not rare condition that is most common in children younger than 10

**Table 131-1**     **Differential Diagnosis of Back Pain**

INFANTS	CHILDREN	ADOLESCENTS
Diskitis Leukemia, lymphoma Vaso-occlusive crisis Osteomyelitis Trauma	Diskitis Tethered cord Osteomyelitis Ankylosing spondylitis Vaso-occlusive crisis Leukemia, lymphoma Ewing sarcoma Osteoid osteoma Spinal tuberculosis	<b>Acute</b> Muscle, ligament strain Lumbar disk disease Apophyseal ring fractures Sciatica Piriformis syndrome Osteomyelitis Epidural abscess Spinal tuberculosis <b>Chronic</b> Spondylolysis Spondylolisthesis Scheuermann kyphosis Facet, vertebral dysfunction Sacroiliac dysfunction Lumbar disk disease Spinal stenosis Spondyloarthropathy Tumor or malignancy Soft tissue strain Functional (nonorganic)

years (mean age, about 6 years). Diskitis is an inflammatory process presumed to be a bacterial infection in the intervertebral disk space. Vertebral osteomyelitis usually affects school-aged children and teenagers and presents as severe back pain and systemic symptoms. A family history of rheumatoid disease should prompt consideration of ankylosing spondylitis. In the presence of sickle cell disease, a vaso-occlusive crisis is a strong consideration. Back pain on walking may be the only sign of a tethered cord. An underlying leg-length discrepancy of any cause may result in chronic or recurrent low-back pain from musculoligamentous strain.

### Adolescents

Classifying the causes of back pain in adolescents as acute or chronic is helpful (Table 131-1). In adolescent patients, a diagnostic consideration of acute back pain caused by muscular or ligamentous strain is reasonable. Other causes of acute back pain include lumbar disk disease, apophyseal ring fractures, vertebral osteomyelitis, epidural abscess, and sciatica caused by piriformis syndrome. The adolescent who has chronic pain (>3 weeks) may still have a strain, but stronger consideration should be given at this point to spondylolysis or spondylolisthesis, which are the most common identifiable causes of low-back pain in this age group. The most frequent cause of spondylolysis is a stress fracture of the pars interarticularis (posterior arch) of the spine, thought to be acquired through repetitive extension loading. Athletes who participate in gymnastics, dance, cheerleading, football, and diving are at highest

risk. For example, ballet dancers, as a group, as well as football players (offensive lineman), have great flexibility but may be predisposed to lumbar lordosis by postural demands and relatively weak core musculature, possibly making them prone to spondylolysis and disk disease. Individuals with benign hypermobility syndromes may also be at risk. Less commonly, spondylolysis can be an asymptomatic congenital deformity. Spondylolisthesis is the anterior movement of one vertebral body on top of another, usually L5 on S1, as a result of bilateral spondylolysis.

Chronic low-back pain, especially in adolescent athletes or others who have cumulative trauma, may indicate lumbar disk disease. Other chronic causes of back pain in this age group include Scheuermann kyphosis, facet or vertebral dysfunction, sacroiliac dysfunction, spinal stenosis, the spondyloarthropathies (ie, ankylosing spondylitis, psoriatic arthritis, Reiter syndrome, arthritis of inflammatory bowel disease that with the exception of psoriatic arthritis can be classified as enthesitis-related juvenile idiopathic arthritis), and tumor or malignancy. Chronic back pain can also be a disorder of the soft tissues of the back, postulated to be caused by a combination of repetitive strain, genetic predisposition, and environmental factors. Assessing for discrepancy in leg lengths and for tight hamstrings is advisable because both alter the dynamic stress put on the muscles and ligaments of the low back. Modifiable contributing factors may include prolonged seated posture, forward bending of the spine while sitting at a desk for long periods, or carrying an excessively heavy backpack (>10%–20% of body weight).

## PSYCHOSOCIAL CONSIDERATIONS

Although malingering or the use of pain symptoms for secondary gain may be relatively common in adults, it should not be a strong consideration in the diagnosis of back pain in children or adolescents. Back pain is not as common a somatoform symptom among adolescents as is headache, abdominal pain, or chest pain. If a thorough diagnostic evaluation of chronic back pain in an adolescent is unrevealing and the usual management involving exercise and stretching is not beneficial, then a psychosocial or nonorganic cause should be considered. The Waddell test, a series of 5 questions, may be used to help determine whether significant psychological stress is associated with chronic low-back pain.

If 3 or more of the following 5 criteria are present, then the test is considered positive:

1. Inappropriate tenderness that is superficial or wide-spread
2. Pain on pressing the top of the head or on passive rotation of shoulders and pelvis
3. Distraction signs such as inconsistent performance between straight-leg raising in the seated and the supine positions
4. Strength and sensory loss patterns that do not fit with accepted neuroanatomy
5. Overreaction during the physical examination

## EVALUATION

### Infants, Children, and Adolescents

The age of the patient is a critical factor in the diagnostic evaluation, with the extent and urgency of evaluation usually being greater for preadolescent patients. The duration of symptoms is an additional factor because chronic pain, even in adolescent patients, is uncommon and may indicate structural or serious underlying disease. The evaluation of acute or chronic back pain should always include motor, sensory, and reflex examination to help differentiate any nerve root involvement (Figure 131-1).

Chronic pain should prompt a diagnostic evaluation possibly to include rectal examination for sphincter tone loss, radiographs of the spine (anteroposterior, lateral, and oblique views), uric acid, lactate dehydrogenase, white blood count, sedimentation rate, C-reactive protein, and urinalysis and urine culture. Infants, young children, or adolescents who have fever and back pain must be considered as having an infectious, inflammatory, or neoplastic process until proved otherwise. Diagnoses that should be considered include diskitis, vertebral osteomyelitis, ankylosing spondylitis, pyelonephritis, vaso-occlusive crisis in a patient who has sickle cell anemia, acute lymphoblastic leukemia, Ewing sarcoma, and Hodgkin lymphoma. Spinal tuberculosis (Pott disease) is rare but should be considered when back pain is accompanied by low-grade fever.

A child with diskitis is typically uncomfortable in an upright posture, may refuse to walk, or may have pain when bending forward. Even in the absence of fever, a child who refuses to walk, particularly a preschooler, should be evaluated promptly for diskitis. Typically,

**Figure 131-1** Sensory, motor, reflex grid. (From Lewis RC. Primary Care Orthopedics. New York: Churchill Livingstone; 1988, with permission from Elsevier.)

diskitis is associated with an elevated erythrocyte sedimentation rate and a high white blood cell count; plain radiographs of the spine may show narrowing of the disk space. In a recent review, 76% of children with diskitis had changes evident on plain radiographs; however, plain radiographs are often negative in the first 2 to 3 weeks of the disease. If a second imaging test is needed, magnetic resonance imaging (MRI) is generally thought to be sensitive in identifying diskitis.

Weight loss, bone pain in other locations, bruising, organomegaly, or adenopathy should prompt aggressive diagnostic evaluation for malignancies such as leukemia, lymphoma, or sarcomas. Especially in the presence of fever or other systemic signs and symptoms, acute leukemia and lymphoma are serious concerns and must be ruled out.

A child with nocturnal back pain, even if relieved by nonprescription analgesics, should be evaluated for osteoid osteoma or osteoblastoma with a bone scan if plain radiographs are normal. Primary vertebral tumors almost always are visible on plain radiographs, but computed tomography (CT) or MRI may be needed.

Fever accompanied by back pain should prompt an aggressive diagnostic evaluation and orthopedic surgery consultation because aspiration and culture to evaluate for possible vertebral osteomyelitis should be considered. Dysuria, urinary urgency, or urinary frequency, especially if accompanied by fever, warrants consideration of pyelonephritis.

**Figure 131-2** One-leg hyperextension test (stork test).

Idiopathic scoliosis usually does not cause back pain in children. Scoliosis with pain should raise concern about an alternative cause, including malignancy in the region of the spine or a benign osteoid osteoma.

### Adolescents

Muscular or ligamentous strain begins to become common during adolescence. The typical presentation is low-back pain of 3 weeks' or less duration, with or without recollection of an acute injury, that is exacerbated by postural changes or specific movements. Associated signs and symptoms such as neurologic deficits of the lower extremities; limited straight-leg raising; sciatic pain; bowel, bladder, or sexual dysfunction; fever; weight loss; adenopathy; urinary urgency or frequency; scoliosis; or marfanoid habitus should be absent. The pain is exacerbated by lifting, stooping, and exercising. Radiologic studies are not needed if muscular or ligamentous strain is thought to exist. However, very localized tenderness in the spine after an injury (eg, motor vehicle crash, athletic trauma) warrants radiologic evaluation for compression fracture. Plain radiographs (anteroposterior and lateral) should be ordered initially.

Low-back pain associated with excessive lordotic curvature, especially in an athlete subjected to repetitive extension loading (eg, gymnasts, football linemen), may indicate spondylolysis or spondylolisthesis. Spondylolysis may be unilateral or bilateral and is

**Figure 131-3** Scotty dog with a collar. (From Smith JA, Hu SS. Management of spondylolysis and spondylolisthesis in the pediatric and adolescent population. *Orthop Clin North Am.* 1999;30(3):487–499, ix, with permission from Elsevier.)

most common at L5. Symptoms of spondylolysis are not usually acute; it more commonly exhibits as a gradual worsening of back pain on extension, usually in an athlete during the growth spurt or after intense training. Pain can be reproduced reliably by having the patient hyperextend the back while standing on one leg (the stork test) (Figure 131-2). The sensitivity of the stork test is modest, however, and a negative stork test should not be relied on to rule out an active spondylolysis. The patient usually has no pain with flexion, rotation, or lateral bending of the back. Hamstring tightness is a common associated finding. Plain radiographs of the lumbar spine should be ordered (anteroposterior, lateral, oblique views). The *Scotty dog with a collar* is visualized on the oblique radiographs (Figure 131-3). Normal plain radiographs alone do not rule out spondylolysis. One study reported that oblique views detected only 32% of spondylolyses detected on CT. A single-photon emission computed tomography (SPECT) scan should be ordered if the diagnosis is highly suggested. A positive plain radiograph with a negative SPECT scan is indicative of a nonmetabolically active spondylolysis that may not be the cause of the patient's back pain. Back pain on extension with normal plain radiographs and SPECT scan is usually from facet or vertebral dysfunction.

Spondylolisthesis may be accompanied on physical examination not only by excess lumbar lordosis but also by the sensation of a shelf at the base of the lordotic curvature, where the lower of the 2 affected vertebrae has held its position while the upper vertebral body slipped forward. The anterior slippage is diagnosed and staged for treatment purposes on the lateral plain radiographs. In rare cases, radiographs will reveal congenital absence of a lumbosacral articular process.

**Figure 131-4** Slump test. (From Reider B. *The Orthopedic Physical Examination*. Philadelphia, PA: WB Saunders; 1999, with permission.)

Accompanying neurologic symptoms, including radicular pain down the leg, numbness or tingling, bowel or bladder problems, erectile dysfunction, or loss of sphincter tone on rectal examination, may indicate lumbar disk herniation or other nerve compression and should prompt an urgent evaluation and referral. Symptoms are typically worsened by mechanical strain, as with lifting or coughing. A positive straight-leg raise test or a *slump test* (Figure 131-4) is highly suggestive of nerve root compression. Using cervical flexion to accentuate the patient's symptoms during straight-leg raising may add to the test's sensitivity. Any reproduction of the patient's usual symptoms during testing before 60 degrees of hip flexion, or marked asymmetry in symptoms, should be considered a positive test. Pain after 60 degrees or limited to the posterior thigh is more likely caused by hamstring tightness.

A spondyloarthropathy should be suspected when there is limited lumbar flexion (modified Schober test), tenderness at entheses (particularly the Achilles-calcaneal entheses, the origin or insertion of the plantar fascia, or the base of the fifth metatarsal), pain in the sacroiliac (SI) area with flexion-abduction and external rotation (an abnormal FABER test), or tenderness over the SI joints. MRI with gadolinium of the SI joints and ultrasonography of the entheses can confirm local inflammation. The presence of HLA-B27 antigen is not diagnostic because it is present in 10% to 30% of individuals of European ancestry.

Scheuermann disease, or butterfly's back, typically exhibits in an adolescent, particularly a competitive swimmer, with thoracic back pain after exercise or late in the day. Patients have rigid thoracic kyphosis on examination and pain worsened by forward flexion. It must be differentiated from postural kyphosis, which is commonly seen in adolescents. Postural kyphosis is a flexible kyphosis that disappears on forward flexion and conscious postural straightening. Scheuermann disease is confirmed by anterior wedging of 5 degrees or greater in 3 or more contiguous vertebrae shown on lateral plain spine radiographs. Oblique radiographs also should be obtained because spondylolysis is associated with Scheuermann disease.

Stigmata of Marfan syndrome include joint hyperextensibility, pectus excavatum, pes planus, dislocated lenses, hernias, arachnodactyly, and scoliosis. The scoliosis may result from a dural ectasia or widening of the subarachnoid space in the lumbar area, which has been associated with low-back pain in adolescents and young adults. Patients who have Marfan syndrome are also at increased risk for spondylolysis.

## MANAGEMENT

Pain that is acute and lasting fewer than 3 weeks, especially with a history of musculoskeletal injury, may be managed expectantly in many cases, whereas more chronic pain in a child or adolescent demands further

investigation. When back pain results from an underlying disorder, treatment of the pain itself should be undertaken in addition to treatment of the primary condition.

### Infants

Treatment for diskitis is variable, depending on its cause. Most experts recommend parenteral followed by oral antibiotic administration, if evidence of bacterial infection exists, and relative rest to promote pain control. Staphylococcal infection is the most common cause of vertebral osteomyelitis and should be treated with antibiotics, rest, and a prompt orthopedic surgery consultation.

### Children

Treatment for diskitis and osteomyelitis in children is the same as that for infants. Management of patients with ankylosing spondylitis is best coordinated by a pediatric rheumatologist, who will often use anti-inflammatory medications with physical and occupational therapy. Treatment of vaso-occlusive crisis entails pain management, hydration, and physical therapy. Leukemia, lymphoma, and Ewing sarcoma should be managed by a pediatric oncologist. Pain from osteoid osteoma is typically relieved with nonsteroidal anti-inflammatory agents, and patients should be referred to a pediatric orthopedic surgeon for possible excision or ablation.

### Adolescents

When the adolescent exhibits back pain acutely after an injury that is thought to be a muscular or ligamentous strain, the PRICEMMMS mnemonic (protection, relative rest, ice, compression, elevation, medication, motion, modalities, strength) should be used. Bed rest, which has been shown to delay recovery, should be discouraged. Continuous-frequency ultrasound and massage are often helpful. Pain-free activity may be resumed gradually, and low-back and hamstring flexibility, as well as the strengthening of the core musculature (abdominal area, hip, and back) with an exercise ball, Yoga, or Pilates exercises, should be emphasized.

Evidence indicates that full sit-ups with the feet fixed and the knees bent, by using hip flexors rather than abdominal muscles, increase intervertebral disk pressure and should be discouraged. The goal of abdominal muscle strengthening is to reduce pelvic tilt and its accompanying tendency toward lordosis and low-back strain. Because decreased strength and endurance of spinal extensor muscles is associated with low-back pain, extensor exercises such as raising the torso and head off the floor or exercise ball while lying prone are recommended. These same exercises, and stretching after warming the muscles by gentle exercise or moist heat, are recommended for chronic low-back pain of muscular origin. Proper posture should also be taught, and backpack weights should not exceed 10% to 20% of the person's body weight. Acupuncture may be a useful adjunct for chronic back pain. If a leg-length discrepancy is discovered, a heel lift as well as physical

therapy to reduce any accompanying flexion contractures at the knee and hip and genu valgus could be of benefit.

The treatment of spondylolysis is controversial and may best be managed by a pediatric sports medicine specialist or orthopedic surgeon. All regimens include the initial cessation of extension-loading activities while providing symptomatic relief and physical therapy that promotes abdominal strengthening and hamstring stretching (the Williams program). Thoracolumbar bracing to prevent extension has been shown to be helpful in some studies; however, others showed no difference in outcomes with or without the use of a brace. Some experts advocate restricting extension activities without a brace. When bracing is implemented, it can be used for up to 6 months or until the patient is pain free with extension. Bone stimulators have been used as adjunctive therapy.

Treatment of the spondyloarthropathic conditions involves anti-inflammatory and immunomodulatory therapies along with physical therapy, and the patient should be referred to a pediatric rheumatologist. Treatment for Scheuermann disease is usually conservative, including physical therapy with strengthening and stretching exercises, avoiding painful activities, and analgesic medication if needed. Thoracolumbar bracing and surgery may be indicated if kyphosis is more than 60 degrees. Patients should be referred to an orthopedic surgeon (pediatric or spinal) for failure of conservative management, intractable pain, or progression of the kyphotic deformity.

Referral to a mental health professional may not be necessary for functional or nonorganic back pain. If the family has a high degree of trust with the physician, then a sensitive evaluation of family and social factors may be an effective first step. In these cases, the physician should not assume that the pain is feigned but rather consider it as a very real physical symptom rooted in psychological or emotional distress. At the very least, chronic pain and its accompanying disability can, of itself, lead to psychological distress, which should be addressed openly by the physician.

### WHEN TO REFER

- Abnormality of posture or gait
- Neurologic findings
- Persistent pain in a preteen
- Pain unrelated to activity or on awakening from sleep
- Functional disability (decreased play or sports activity)
- Diagnosis and evaluation are outside of the primary care physician's scope of expertise

### WHEN TO ADMIT

- Whenever a prompt and thorough outpatient diagnostic assessment cannot be completed for a child who has back pain and associated fever or neurologic findings

## TOOLS FOR PRACTICE

### Engaging Patient and Family

- *Backpack Safety* (fact sheet), American Academy of Pediatrics ([www.healthychildren.org/English/safety-prevention/at-play/Pages/Backpack-Safety.aspx](http://www.healthychildren.org/English/safety-prevention/at-play/Pages/Backpack-Safety.aspx))

## Chapter 132

# CARDIAC ARRHYTHMIAS

J. Peter Harris, MD

Arrhythmias in young people are common and may occur as a result of normal rhythm variations, premature beats, atrial or ventricular tachyarrhythmias, or conduction defects. They can occur at any age, and their clinical implications range from benign to lethal. Newer diagnostic modalities such as event recorders to capture infrequent episodes have enhanced our ability to detect arrhythmias. Empirical therapy without arrhythmia identification does not meet the

current standard of practice. A 12-lead electrocardiogram (ECG) should always be obtained when an arrhythmia is suspected, because electrophysiologic alterations may be quite subtle and not always identified on a rhythm strip. A thorough family history is required, with particular emphasis on sudden and premature death, syncope, seizures, and recurrent arrhythmias.

Infants with arrhythmias may have nonspecific signs and symptoms such as fatigue, malaise, poor feeding, nausea, and pallor. Older children tend to exhibit more specific symptoms such as palpitations (the disquieting awareness of the person's own heartbeat), lightheadedness, syncope, visceral chest pain, and dyspnea.

Premature beats and supraventricular tachyarrhythmias in infancy may be noted incidentally on a visit for other reasons, but, more commonly, infants with supraventricular tachycardia (SVT) present with signs and symptoms of congestive heart failure: tachypnea, dyspnea, truncal diaphoresis, diminished pulses, pallor, hepatomegaly, and poor feeding. Older children and adolescents are able to verbalize discomfort, including palpitations, chest pain, dyspnea, and nausea, with various forms of SVT. Ventricular tachyarrhythmias often compromise cardiac output to a greater degree than SVT and have more overt signs of congestive failure, chest pain, syncope, dyspnea, and palpitations. Myocardial dysfunction is usually related to increased oxygen demand owing to the tachycardia, inadequate time for ventricular filling, ischemia from insufficient time for diastolic coronary perfusion, and loss of atrioventricular synchrony. Infants and children with moderate or severe bradycardia from advanced second-degree and complete heart block also display signs and symptoms of inadequate cardiac output, including fatigue, reduced exercise capacity, pallor, presyncope, and syncope.

## APPROACH TO ARRHYTHMIAS

As a part of the systematic approach to ECG interpretation, the cardiac rhythm should be analyzed in an organized fashion. The answers to the following 4 questions will define most arrhythmias:

1. Is the rhythm fast or slow?
2. Is the rhythm regular or irregular?
3. Are the QRS complexes narrow or wide?
4. What is the relationship between the P waves and the QRS complexes?

## NORMAL RHYTHM VARIATIONS

Recognizing normal rhythm variations allays patient and parental anxiety and avoids unnecessary investigations and interventions. For instance, sinus arrhythmia (phasic respiratory variations of sinus rate with inspiratory acceleration and expiratory slowing) is common in childhood; so too is wandering atrial pacemaker, usually noted with slower heart rates and characterized by different P-wave morphologies. These rhythm variations are related to alterations in vagal tone.

A wide range of heart rates is present in the young. Sinus tachycardia has been documented at rates of 230 to 250 beats per minute during infancy, but a rate in excess of 200 beats per minute in a teenager who is not involved in maximal exertion would be abnormal. Sinus bradycardia is a sinus rate below what is expected for a patient's age. A sinus rate below 100 beats per minute in an awake neonate would be abnormal, but during sleep, rates down to 80 beats per minute are commonly observed on ECG monitoring. Brief dips into the 60- to 80-beats-per-minute range are also observed in sleeping neonates during normal, vagally induced episodes of junctional rhythm that arise from either the atrioventricular node or the bundle of His and that are characterized by a narrow QRS without a preceding P wave. A highly conditioned adolescent endurance athlete may have a resting heart rate of 40 beats per minute or less. Table 132-1

**Table 132-1** Bradycardia by Age and Stat

AGE	HEART RATE
<b>SURFACE ELECTROCARDIOGRAM</b>	
Neonates and infants	<100 beat/min, awake
Children to 3 years	<100 beats/min
Children 3–9 years	<60 beats/min
Adolescents 9–16 years	<50 beats/min
Adolescents >16 years	<40 beats/min
<b>AMBULATORY (HOLTER) MONITORING</b>	
Neonates and infants	<60 beats/min, sleeping; 80 beats/min, awake, quiet
Children 2–6 years	<60 beats/min
Children 7–11 years	<45 beats/min
Adolescents >11 years	<40 beats/min
Athletes	<30 beats/min

provides guidelines for the diagnosis of sinus bradycardia on the surface ECG and during ambulatory monitoring.

## PREMATURE BEATS

Premature beats are common, but usually benign, arrhythmias and may arise in the atria, the atrioventricular junction, or the ventricles. By definition, premature beats are early and thus are distinguished from escape or late beats occurring when higher pacemaker cells fail to produce an impulse at the expected interval. Two premature beats in a row constitute a couplet. If every second or third beat is a premature impulse, then a bigeminal or trigeminal rhythm is present.

### Atrial Premature Contractions

Atrial premature contractions (APCs) are characterized by premature P waves with an axis and morphology that are different from the sinus P waves. If an APC occurs when one of the bundle branches is refractory, then the premature beat will be conducted down the other bundle branch, resulting in an aberrant APC with a QRS morphology wider and different from sinus QRS complexes (Figure 132-1). If both bundle branches are refractory, then the APC will not be conducted to the ventricles (blocked APC) but may reset the sinus node with a resultant pause greater than the previous RR interval. If every other beat is a blocked APC (blocked atrial bigeminy) in a newborn infant who is dependent on an adequate heart rate for normal cardiac output, then slowing of the heart rate sufficient to alter feeding and arousal time may be present. T waves are usually smoothly inscribed, and consistent sharp deflections in the T waves may represent P waves (Figure 132-2). APCs usually occur with normally conducted QRS complexes; but if wide beats

**Figure 132-1** Atrial premature contractions (arrows) with normal and aberrant conduction.

**Figure 132-2** Every other beat is a blocked atrial premature contraction (blocked atrial bigeminy) represented by a consistent sharp deflection in the T waves.

are also noted, then the apparently prolonged QRS beats are likely to be aberrant APCs because premature atrial and ventricular contractions rarely occur together, especially in the newborn period.

The incidence of APCs is 50% to 75% in children on Holter monitoring. Most are benign and require no therapy; however, there are occasional associations with myocarditis, atrial stretch, sympathomimetic or other stimulant drugs, intracardiac catheters, and electrolyte disturbances. They are most often without an obvious incitant and are usually not recognized by the child or adolescent. If suppressive therapy is required, then either digoxin or propranolol is suitable.

### Premature Ventricular Contractions

Premature ventricular contractions (PVCs) are less common than APCs but may be present on Holter monitoring in up to 25% of healthy infants, children, and adolescents. PVCs are characterized by a QRS morphology that is different from sinus QRS beats, occur before the next expected sinus beat, and are not preceded by a premature P wave. The QRS duration may be only slightly prolonged. Uniform PVCs have similar morphology to one another, and multiform PVCs have diverse morphology. The designations *unifocal* and *multifocal* are no longer used, because the form of PVCs is now known not to correlate reliably with focus of origin. If a PVC occurs late, at the beginning of the next expected sinus beat, then it will produce a hybrid or fusion beat derived, in part, from the normal conduction pathways and, in part, from the PVC. Fusion beats have a morphology that is intermediate between the sinus QRS and PVC.

Although most PVCs are observed in healthy children and adolescents, PVCs can occur in patients with underlying heart disease, such as myocarditis, hypertrophic and dilated cardiomyopathies, and ventricular dysfunction in congenital cardiac malformations. The new appearance of PVCs in the setting of a febrile illness should raise the question of myocarditis. Other causes include sympathomimetic and street stimulant drugs, electrolyte imbalances, and intraventricular catheters. A 12-lead ECG should always be obtained to assess the premature beat morphology and to look for chamber enlargement but also to calculate the corrected QT interval.

$$QTc = \frac{QT \text{ interval (seconds)}}{\sqrt{\text{Preceding RR interval (seconds)}}}$$

**Figure 132-3** Antegrade conduction over an accessory pathway during atrial fibrillation in a 15-year-old boy with syncope. The short RR intervals represent rapid conduction over the accessory connection and a risk for ventricular fibrillation.

PVCs are considered benign if no evidence of heart disease exists, the QTc is normal ( $\leq 0.44$  second), the family history is not adverse (no sudden premature deaths or cardiac arrests, important arrhythmias, or cardiomyopathies), and the PVCs are uniform in appearance and are either suppressed or not aggravated with exercise. Conversely, the presence of any of these risk factors should prompt referral for further investigation. Because underlying heart disease may be subtle, an echocardiogram to assess cardiac structure and function is usually obtained in referred patients.

Benign PVCs do not require treatment or curtailment of exercise, even if a bigeminal rhythm is present. However, if frequent benign PVCs persist, then cardiology surveillance should be arranged to detect the unusual situation of arrhythmia-induced ventricular dilation or dysfunction, especially if the ectopy burden constitutes more than 5% of the total beats on a 24-hour ambulatory electrocardiogram. PVCs that are not clearly benign require the expertise of a pediatric cardiologist to determine whether there is a need for therapy. Ventricular couplets are assessed in the same manner, but triplets represent ventricular tachycardia and are discussed later in this chapter.

### SUPRAVENTRICULAR TACHYCARDIA

Supraventricular tachycardia (SVT) is common in the young, affecting as many as 1 in 250 children. More than 90% of pediatric SVT is reentrant in nature, involving 2 distinct atrioventricular pathways with differing conduction characteristics and unidirectional block in one pathway. An APC may initiate SVT by entering the unblocked pathway, activating the ventricle, and then re-entering the atrium retrograde through the blocked pathway, completing the reentrant circuit. Most re-entrant SVT in infants and children results from an accessory pathway, but the incidence of atrioventricular nodal reentry increases during adolescence with further development of the atrioventricular node. Wolff-Parkinson-White (WPW) syndrome is present if the ECG demonstrates pregrade conduction through the accessory pathway in sinus rhythm as a short PR interval, delta wave, and wide QRS. The prevalence of WPW syndrome in the general population is 0.15%, but in many affected individuals, no SVT occurs. Patients with asymptomatic WPW syndrome carry a small (0.05%–0.5% per year) but definite risk for sudden death related to rapid antegrade conduction down the accessory pathway if atrial fibrillation occurs (see Figure 132-3).

WPW syndrome (with tachycardia) may be inherited in an autosomal-dominant fashion, and for these individuals the risk for sudden death is substantially increased. Automatic atrial tachycardias account for less than 10% of SVTs in children and tend to be incessant with a variable rate dependent on autonomic tone.

About 50% of patients with SVT present with tachycardia during the first 4 months of life, and 60% of this group will have recurrences, particularly if WPW syndrome is present. Although potentially still inducible at an electrophysiologic study, more than 90% will be free of clinical episodes of tachycardia at 1 year of age. However, as many as one-third of children who have a history of SVT in early infancy and clinical resolution by 1 year of age may have a recurrence at a mean age of 8 years. SVT presenting for the first time in a child 5 years or older implies a likelihood of recurrent episodes of tachycardia as high as 75% to 80%. SVT is usually initiated by an APC or sinus tachycardia in early infancy, but in childhood and adolescence, PVCs and sinus pauses with junctional escape beats are additional initiators. Most children with SVT have a structurally normal heart, but if WPW syndrome is present, there is a somewhat higher incidence of cardiac defects such as hypertrophic cardiomyopathy, Ebstein malformation, or levotransposition of the great vessels.

## PRESENTATION OF SVT

During infancy, SVT may be detected incidentally on a routine examination; more commonly, however, young infants exhibit varying degrees of congestive heart failure related to the rate and duration of tachycardia and the presence of associated heart disease. As a general rule, 25% of infants develop congestive heart failure after tachycardia for 24 hours, and 50% have heart failure after SVT for 48 hours. Often, a history of poor feeding and pallor over several days is present, culminating in respiratory distress. Children older than 5 years are usually able to communicate their distress soon after the onset of SVT—hence the relative rarity of congestive heart failure caused by SVT in older children. The duration of SVT in children and adolescents ranges from a few seconds to several hours. Palpitations are the only symptom in some children; others have lightheadedness, chest discomfort, pallor, diaphoresis, and nausea. SVT-induced syncope is rare. In infancy, the heart rate with SVT may range from 230 to 300 beats per minute but is usually between 260 and 280 beats per minute, in contrast to older patients who typically have rates between 180 and 240 beats per minute. The QRS complexes are usually narrow but may be transiently wide at initiation as a consequence of aberrancy (Figure 132-4). A 12-lead ECG may reveal sharp deflections in the T waves, representing retrograde conduction from the ventricles to the atria through an accessory pathway (Figure 132-5).

## MANAGEMENT OF SVT

If cardiogenic shock is present with SVT, then direct current synchronized cardioversion should be performed; otherwise, adenosine can be administered

through an intravenous bolus of 100 mcg/kg, followed by a second doubled dose if the first dose is ineffective. Adenosine always should be administered with ECG monitoring to detect the rare conversion to a more malignant arrhythmia. If adenosine is ineffective, or if SVT quickly recurs, cardiology consultation is advised. In this circumstance, an infusion of procainamide can be administered to infants and young children after appropriate loading, with a subsequent repeat trial of adenosine. Alternatively, amiodarone (5 mg/kg) may be administered intravenously over 20 to 60 minutes, followed by a repeat bolus if conversion is not achieved with the first dose. In general, in children younger than 1 year, intravenous verapamil and propranolol are contraindicated.

After conversion to a sinus rhythm is achieved, a 12-lead ECG should be repeated to look for evidence of pre-excitation. If WPW syndrome is present, suppressive therapy with propranolol is appropriate. Digoxin and verapamil should be avoided in children with WPW because either medication may shorten the antegrade refractory period of the accessory pathway, allowing more rapid conduction to the ventricles, a potentially fatal scenario if atrial fibrillation develops. If pre-excitation is not present, either digoxin or propranolol has been used with success to prevent recurrences. Many cardiologists currently avoid the use of digoxin because of concerns about unproven efficacy and its potential for toxicity. Beta blockers are not universally effective either and may aggravate congestive heart failure, sick sinus syndrome, or bronchospasm. Other possible medical therapies include flecainide, sotalol, or amiodarone, all of which require hospitalization for drug initiation because of possible proarrhythmic effect. Infants who have SVT are usually treated for 6 to 12 months and then observed in view of the risk for later recurrence. Because of the higher risk for complications, including the prospect that the resultant myocardial scar may grow with the patient and become a subsequent nidus for malignant and often drug-refractory arrhythmias, ablations are not commonly recommended in the first 2 years of life. If surgery for a cardiac defect is contemplated and episodes of SVT have occurred, then preoperative assessment and ablation should be considered to reduce arrhythmia-related postoperative morbidity and mortality.

Depending on the frequency and ease of conversion of episodes, older children and adolescents have 3 therapeutic choices:

1. No therapy other than self-conversion through a supine Valsalva maneuver or headstand
2. Drug therapy, although the duration, adherence issues, and cost of this approach need to be addressed with the family
3. Radiofrequency ablation, currently at least 90% successful but with a chance of a later recurrence

Automatic ectopic tachycardias in childhood are often incessant and relatively drug resistant, with the eventual possible outcome of a tachycardia-induced cardiomyopathy if conversion is not achieved. However,

**Figure 132-4** Transient aberrant conduction at the onset of supraventricular tachycardia during an exercise test in a 14-year-old adolescent. The QRS duration then returns to normal.

**Figure 132-5** Twelve-lead electrocardiogram (ECG) of supraventricular tachycardia in a 2-week-old infant. Consistent sharp deflections in the T waves are present in lead III, indicating retrograde atrial activation via an accessory pathway. A repeat ECG after conversion to sinus rhythm did not reveal any pre-excitation; therefore, a concealed accessory pathway is present. Note also the ST depression in the lateral precordial leads, indicating an element of myocardial ischemia.

spontaneous resolution may occur, especially in patients younger than 3 years.

### ATRIAL FLUTTER

Atrial flutter, a primary atrial re-entrant tachycardia, is seen in a bimodal distribution in newborns and in older children, the latter usually with cardiomyopathies and after repair of complex congenital heart malformations.

In the newborn, the characteristic rapid sawtooth pattern with inverted P waves in the inferior limb leads is found with an atrial rate typically between 350 and 500 beats per minute and variable, commonly 2:1, atrioventricular block, resulting in a mean ventricular rate typically about 200 beats per minute. If the onset is in utero, then hydrops fetalis may develop. After birth, congestive heart failure tends to be less severe than in SVT. Structural cardiac problems are uncommon.

**Figure 132-6** Intra-atrial re-entrant tachycardia before and immediately after adenosine treatment in a 12-year-old boy after a Mustard repair of transposition of the great arteries in infancy. Adenosine produces high-grade AV block revealing but not converting the underlying IART.

Spontaneous conversion may occur within a few hours of birth. Although most require electrical cardioversion, chronic pharmacotherapy is usually unnecessary because recurrences are rare.

Although the typical form of atrial flutter may be seen in older children and adolescents, more common in this age group is a different variety called intra-atrial re-entrant tachycardia (IART), characterized by a slower atrial rate and distinct P waves separated by isoelectric periods. IART is usually seen after repair of complex congenital cardiac lesions (Figure 132-6). Management is often difficult, but if conversion to and maintenance of a sinus rhythm cannot be achieved, morbidity is substantial, with a 4- to 5-fold increase in the risk for sudden death. If an inappropriately rapid heart rate of 100 to 140 beats per minute is noted in an older child after repair of congenital heart defect, a 12-lead ECG should be obtained to look for IART, even if the surgical repair is in the remote past.

### ATRIAL FIBRILLATION

Atrial fibrillation, an irregular tachycardia with variable atrioventricular conduction, is much less common than the other forms of SVT and is seen in older patients with structural heart disease, cardiomyopathies, and alcohol binges. However, the incidence of idiopathic and paroxysmal atrial fibrillation in adolescence may be underestimated. If pre-excitation (WPW syndrome) is present and the accessory pathway is capable of rapid antegrade conduction, atrial fibrillation may conduct quickly to the ventricles, with a resultant decrease in cardiac output, syncope, and the potential for ventricular fibrillation and sudden death (see Figure 132-3).

### VENTRICULAR TACHYCARDIA

Ventricular tachycardia (VT) is defined as 3 or more repetitive excitations arising from the ventricles with a rate more than 120 beats per minute or 25% faster than the sinus rate. The QRS complexes are different from the sinus QRS complexes and are typically wide, except in young infants in whom minimal QRS prolongation (0.08–0.09 second) may be seen. VT may be extremely rapid, up to 500 beats per minute, and slightly irregular because of intermittent sinus capture beats. The differential diagnosis includes SVT with persistent aberrancy (see Figure 132-4) and SVT with antegrade conduction across an accessory pathway (see Figure 132-3), both of which are relatively uncommon. Safety dictates that all wide QRS tachycardias be considered VT until proved otherwise. The presence of similar but isolated PVCs and fusion beats in sinus rhythm assists in establishing the diagnosis, but VT is confirmed by the presence of atrioventricular dissociation (Figure 132-7).

VT in the newborn and young infant is rare, and when it is drug resistant and incessant, a ventricular tumor may be present. Mitochondrial fatty acid  $\beta$ -oxidation disorders can also cause VT in neonates. Predisposing factors in older children and adolescents include myocarditis, repaired and unrepaired congenital cardiac lesions, cardiomyopathies, long QT syndrome, catecholamine- or exercise-induced VT, marked electrolyte imbalances, and use of street drugs (eg, cocaine). In general, VT is a marker for myocardial disease.

Acute management depends on the patient's clinical status, which is determined by the rate and duration of VT and the presence of structural cardiac lesions or

**Figure 132-7** Ventricular tachycardia: wide QRS tachycardia with atrioventricular dissociation.

prior myocardial dysfunction. Hemodynamic compromise dictates electrical cardioversion with 1 to 2 watt-seconds/kg. If reasonable clinical stability is present, then intravenous amiodarone, procainamide, magnesium, or lidocaine can be administered.

Chronic suppressive therapy is predicated on the risk for recurrence, the morbidity and mortality of the type of VT, and the risk-to-benefit ratio of treatment. Beta blockers, sotalol, and amiodarone are commonly used to prevent VT recurrences. Other treatments include implantation of an automatic cardioverter-defibrillator and VT ablation. In contrast to classic VT, accelerated ventricular rhythm is characterized by a rate of 120 beats per minute, or less than 25% faster than the basic sinus rate. Accelerated ventricular rhythm is benign when it occurs in an otherwise normal heart.

## CONDUCTION ABNORMALITIES

First-degree atrioventricular block is a prolongation of the PR interval beyond the upper limit of normal for age, with all impulses conducted. It may be seen in patients who have congenital cardiac malformations (especially atrioventricular septal defects), electrolyte disorders, rheumatic fever, myocarditis, and congenital muscular disorders. Patients receiving antiarrhythmic agents frequently exhibit first-degree atrioventricular block, which is usually benign in most settings.

Mobitz type I second-degree atrioventricular block, also known as *Wenckebach block*, is a progressive prolongation of the PR interval until a dropped ventricular beat (nonconducted P wave) occurs. It is a normal finding in healthy children during sleep and in highly conditioned athletes at rest, circumstances that are associated with a predominance of vagal tone. In general, this entity, when it occurs without exertional symptoms or syncope, is benign.

On the other hand, Mobitz type II second-degree atrioventricular block is characterized by intermittent loss of atrioventricular conduction without preceding lengthening of the PR interval. Because the site of Mobitz type II block is more distally located in the bundle of His (in contrast to type I, in which the site of block is in the atrioventricular node), there is greater risk for progression to complete atrioventricular block. The presence of type II block implies an abnormal conduction system with greater risk for associated

symptoms and threatening complications, so referral to a cardiologist is appropriate for ongoing medical surveillance and evaluation for potential pacemaker implantation.

Complete atrioventricular block (CAVB), in which no atrial impulses are conducted to the ventricles, occurs in 1 of 10,000 to 20,000 live-born infants and may be acquired or congenital. Acquired block is usually a consequence of conduction system injury at the time of repair of congenital cardiac malformations but can also be seen in myocarditis, including Lyme disease, and with ingestion of beta blockers, clonidine, opioids, and sedatives. About 50% of newborns who have complete congenital atrioventricular block (CCAVB) have underlying complex congenital heart malformations, particularly levotransposition of the great vessels and complex atrioventricular septal defects. Even with permanent pacing, the mortality rate of CCAVB in the setting of structural heart disease is high (>75%). The other 50% of neonates with CCAVB have immune-mediated block associated with the passage in utero of immunoglobulin G SS-A/Ro and SS-B/La antibodies from the mother who has overt or occult autoimmune disease. When the fetus is exposed to these maternal antibodies, particularly to high levels ( $\geq 100$  U/mL) of maternal anti-Ro antibodies between 15 and 24 weeks of gestation, there may be fibrotic replacement of atrioventricular nodal tissue with consequent second-degree block or CAVB (Figure 132-8). Fewer than 5% of infants born to mothers who have autoimmune disease develop CCAVB. Infants without CCAVB born to anti-Ro/SS-A-positive mothers with autoimmune disease may have QT prolongation and sinus bradycardia. If a mother bears a child who has CCAVB, the risk in future pregnancies is 15%. An immune-mediated myocarditis may also occur in fetuses exposed to maternal anti-Ro and anti-La antibodies, with possible development of a postnatal dilated cardiomyopathy (endocardial fibroelastosis).

Risk factors for fetal, neonatal, or late death with CCAVB include fetal hydrops, premature birth, the presence of complex structural heart disease, a prolonged QT interval seen in up to 25% of affected patients, congestive heart failure, ventricular ectopy, atrioventricular valve insufficiency, and a low or decreasing ventricular rate (55 beats per minute or less in a neonate). In view of the risk for mortality, early

**Figure 132-8** Complete congenital atrioventricular block in a newborn infant whose mother has Sjögren syndrome. The atrial rate is 150 beat/min, and the ventricular rate is 60 beats/min. The QRS duration is normal.

pacemaker implantation is advised if any of these risk factors or signs of an inadequate cardiac output is present. An infusion of isoproterenol can be administered, if necessary, to increase the heart rate while awaiting pacemaker therapy but should not delay implantation. In patients who do not require pacemaker implantation in early infancy, pacing usually becomes necessary in adolescence.

### SUDDEN CARDIAC DEATH

Sudden cardiac death, a rare but devastating event in the young, strikes approximately 1 in 100,000 children and teenagers, with the highest incidence in mid-adolescence. In decreasing order of frequency, predisposing factors include the following:

1. Repaired complex congenital heart malformations
2. Cardiomyopathies
3. Myocarditis
4. Congenital coronary artery anomalies (especially origin of the left main coronary artery from the right sinus of Valsalva)
5. Primary arrhythmias such as long QT syndrome (LQTS), WPW syndrome, and catecholamine-sensitive polymorphic VT

LQTS is a familial, clinically and genetically heterogeneous ion channel cardiac disorder that prolongs repolarization and may cause syncope, seizures, and sudden death as a consequence of polymorphic VT (torsades de pointes). The autosomal-dominant Romano-Ward subcategory, which accounts for 95% of patients with LQTS, is related to a heterozygotic mutation on chromosomes 11, 7, 3, 4, or 21. The remaining 5% are characterized by homozygotic mutations on chromosome 11 leading to the autosomal-recessive Jervell and Lange-Nielsen (JLN) syndrome, which is characterized by marked prolongation of the corrected QT intervals and congenital deafness. Patients with JLN syndrome have a greater degree of QTc prolongation and a substantially higher incidence of sudden death compared with patients with the much more common Romano-Ward variant. Potassium-channel function is affected by mutations on chromosomes 11, 7, 4, and 21, whereas the sodium channel is perturbed as a consequence of mutations on chromosome 3.

The incidence of LQTS is estimated at 1 in 2,500 individuals, with no gender predisposition, but the incidence may be underestimated because of incomplete genetic ascertainment. The annual mortality rate after onset of symptoms in untreated young patients is 1% to 5%, with a nearly 10% risk for sudden death as the initial symptom. The cumulative probability of a cardiac event (predominantly syncope) occurring in patients who are genotyped LQT1, 2, and 3 by 15 years of age ranges between 10% for patients with LQT3 and 69% for those with LQT1. LQTS has been identified as a rare cause of the sudden infant death syndrome. The highest risk for sudden death occurs in patients with a history of syncope and a QTc of more than 500 milliseconds. Syncope, atypical seizures, or cardiac arrest usually occur during exertion or emotional stress, except for long QT3 subtype events, in which symptoms predominantly occur at rest. Other than bradycardia, the physical examination is usually normal. LQTS is defined by a corrected QT interval in excess of 460 milliseconds, with a borderline QTc defined by an interval of 440 to 460 milliseconds. In general, the longer the QTc, the greater the risk for polymorphic VT. The differential diagnosis of QTc prolongation also includes electrolyte abnormalities such as hypokalemia, hypocalcemia, and hypomagnesemia. Myocardial ischemia or injury, acute central nervous system events, and cardiomyopathies may be associated with mild QTc prolongation. Cisapride, imipramine, pentamidine, and intravenous erythromycin may also prolong the QT interval. Management of LQTS includes beta-blocker therapy, restriction from competitive sports, avoidance of sympathomimetics and drugs capable of prolonging the QTc, and avoidance and rapid correction of electrolyte abnormalities. More invasive management is often necessary, including pacing, left stellate ganglionectomy, and implantation of an internal cardiac defibrillator. Gene-specific therapy with potassium channel opening agents and sodium channel blockers is on the horizon.

Beyond infancy, 25% of sudden cardiac deaths in the young occur during exercise; most occurrences are electrical in nature, with ventricular fibrillation as

the final common pathway. Athletic risk may be stratified by asking 2 critical questions in pre-sports clearance evaluations: (1) Has the patient ever passed out, had visceral chest pain, or experienced symptomatic palpitations during strenuous exercise? (2) Has any family member died suddenly and unexpectedly before the age of 35 years? An affirmative answer to either question should prompt a referral to a cardiologist before participation in competitive sports. For any child or adolescent who collapses suddenly with no discernible cardiac output, rapid resuscitation including early defibrillation is mandated. Automatic external defibrillators that are available in some school systems have already begun to decrease the incidence of sudden cardiac death in the young.

### WHEN TO REFER

- Arrhythmias associated with presyncope, syncope, chest pain, or a sense of doom
- Arrhythmias associated with repaired or unrepaired congenital heart disease or cardiomyopathies
- Family history of premature (<35 years) sudden cardiac death
- Persistent or repetitive bradycardias or tachycardias
- Premature ventricular beats that increase with exercise
- Asymptomatic WPW syndrome

### WHEN TO ADMIT

- Arrhythmias associated with congestive heart failure, syncope, or low cardiac output
- Symptomatic high-grade atrioventricular block
- Difficult-to-control SVT, atrial flutter
- VT
- Heart disease with syncope, aborted sudden death

## Chapter 133 CHEST PAIN

Scott A. Schroeder, MD

Although chest pain from cardiac disease in children is extremely rare, few symptoms result in more fear and anxiety in children and their parents. Undiagnosed cardiac disease causes chest pain in less than 5% of patients, and if children with preexisting heart disease are excluded, then cardiac abnormalities are found in less than 1% of patients. Although chest pain from cardiac disease occurs in a few children, much of the pediatrician's evaluation and teaching will be focused on convincing families that the heart is normal. If the care of a child with chest pain is managed inappropriately, then grief, anxiety, restriction of activities, and distrust by the family may result. However, a thorough history and physical examination will usually uncover the cause of the chest pain and will almost always allow the physician to state emphatically that the chest pain in this case is certainly not from heart disease.

### DIFFERENTIAL DIAGNOSIS

Of children and adolescents with chest pain, by far the largest number have musculoskeletal chest wall

trauma or other conditions identified as the source of the pain. Pulmonary diseases—pneumonia, asthma, pneumothorax, and cough itself—account for approximately one-fifth of cases, and the rest are the result of hyperventilation or psychiatric causes, gastrointestinal disorders, and, finally, cardiac disease. Approximately 15% of cases remain idiopathic. However, most studies on the causes of chest pain in children originate in pediatric emergency departments and pediatric cardiology clinics, and therefore these studies have not rigorously looked for the presence of esophageal disorders or reactive airway disease, both of which have been shown to be common in children with idiopathic chest pain.

## **PATHOPHYSIOLOGIC FEATURES OF CHEST PAIN**

Because numerous organ systems are within the thorax, and because of the confusing overlap of sensory inputs from the various tissues in the chest, a systematic approach to the thorax is essential to determine the source of the child's pain. Pain from the chest wall and the supporting musculoskeletal structures is transmitted from these inflamed or irritated tissues to the central nervous system through the primary sensory afferents that terminate in the dorsal root ganglia. Spinal neurons then transmit the sensation from the inflamed chest wall tissues to the brain, where it is perceived as a sharp, localized pain. This feature is why chest wall pain (eg, from costochondritis or trauma) is sharp, localized, and easily reproduced on palpation.

Spinal neurons that receive input from the organs within the thorax also receive sensory input from the thoracic dermatomes. This overlap of sensory input leads to the phenomenon of *referred pain*, which often makes the evaluation of chest pain challenging. Diffuse, poorly localized chest pain can originate from any of the organs within the thorax. Inflammation of the structures that pass through the mediastinum results in pain over dermatomes T1 to T4, from the retroclavicular to the retrosternal regions. Pain over dermatomes T5 to T8, especially in the xiphoid area, suggests lower chest wall or diaphragmatic irritation or even intra-abdominal disease. Because both the intercostal nerves and the phrenic nerve innervate the diaphragm, peripheral diaphragmatic irritation causes pain in the lower anterior chest or epigastric regions, and central diaphragmatic inflammation results in ipsilateral shoulder pain because of its innervation by the phrenic nerve. The pericardium, positioned on the central diaphragm, has pleural connections and is innervated by the phrenic, vagus, and recurrent laryngeal nerves. Therefore, when the pericardium is inflamed or infected, sharp substernal pain can occur. The pain of pericarditis may be limited to the sternal and precordial areas; however, if the left lobe of the diaphragm is irritated, then pain will be referred to the ipsilateral shoulder or neck. Pleural pain results from distention or inflammation of the pleura that can occur during the course of pneumonia, pneumothorax, or empyema. Pain from pleural inflammation is

aggravated by respiratory movements. The pain is characterized as well localized and sharp, exaggerated by coughing or deep inspiration. The pain associated with a pneumothorax can be pleuritic in nature, or it can be referred to the ipsilateral shoulder. Pleurodynia is a specific cause of pleuritic chest pain heralded by fever and associated with coxsackievirus B; an idea of its intensity comes from its apt nickname as “the devil’s grip.”

The pain associated with esophageal disorders can seem indistinguishable from that associated with myocardial ischemia because the sensory afferents from the esophagus are through the cardiac and esophageal plexi as well as the sympathetic trunk. Within the lungs, sensory input exists only from the larger airways and parietal pleura; thus, the pain arising from pulmonary parenchymal disease results from inflammation of or traction on contiguous structures.

## **EVALUATION**

### **History**

Because pathognomonic findings are rare on physical examination in the evaluation of a child with chest pain, a detailed history will help focus the differential diagnosis, develop a logical intervention, and allow the child and family to voice their concerns. A meticulous history should address the nature of the pain as well as the child's response to the pain. If possible, children should describe the pain in their own words, and they should be asked what they think is causing the pain. Along with a description of the location, duration, radiation, and quality of the pain, the pediatrician should elicit any associated signs and symptoms, as well as any aggravating and alleviating factors, and attempt to uncover the family history and dynamics. To many adolescents, chest pain is synonymous with heart disease; therefore, this issue should be addressed, and if no cardiac cause is discovered, then the physician should unequivocally state to the adolescent and the family that the heart is normal.

Pain that occurs with exercise points toward either a cardiac or a respiratory cause. If the pain awakens the child from sleep, then the cause might be respiratory, cardiac, musculoskeletal, or gastroesophageal, but it is never psychological. When the pain is poorly localized or is associated with recurrent somatic complaints or family or school stress, and when a family history of chest pain can be found, a psychogenic source of the pain is likely. Conversely, deep, poorly localized pain that radiates to the neck or shoulders is characteristic of visceral pain. Superficial sharp pain that is exacerbated by lifting or movements of the torso suggests musculoskeletal pain.

Peripheral pain that increases with inspiratory efforts originates from pleural inflammation. Questions regarding trauma to the chest wall should always be asked, and even if the trauma occurred 1 to 3 months before the pain, it should not be discounted because the pain might represent a posttraumatic pericardial effusion. Sharp pain that decreases when the child

leans forward is characteristic of pericardial inflammation. Children with a family history of Marfan or Turner syndromes, as well as those with a history of Kawasaki disease or congenital heart disease, warrant referral to a pediatric cardiologist.

Even if the history is highly suggestive of the cause for the chest pain, the pediatrician should be careful and thorough because the potential exists for 2 different causes of the pain. Children with asthma can also have gastroesophageal reflux. Children with sickle cell disease who develop acute chest syndrome may have chest pain as a result of medication-induced gastritis, vaso-occlusive crisis, or asthma.

### Laboratory Evaluation

Laboratory tests are usually not helpful in establishing a specific diagnosis; therefore, a thorough history and physical examination should guide the physician in ordering tests. In most cases, chest radiographs and electrocardiographs will only confirm what is suspected clinically. If a child has a fever, acute onset of chest pain, and an abnormal cardiac examination suggestive of pericarditis, then a chest radiograph and electrocardiogram are indicated. If a child has fever, tachypnea, chest pain, and decreased breath sounds over a segment of the lungs, then a chest radiograph is appropriate to determine whether a pneumothorax, a pneumonia, a pleural effusion, or other pulmonary disease is present. If the pain occurs with exercise, then exercise testing or spirometry may help uncover underlying asthma or exercise-induced bronchospasm. One cause of idiopathic chest pain may be an esophageal disorder. Signs and symptoms of children with chest pain who warrant hospitalization or specialty evaluation are listed in Box 133-1.

## SPECIFIC CAUSES OF CHEST PAIN IN CHILDREN

### Musculoskeletal and Chest Wall Conditions

After a determination has been made that the child is in no distress, inspection of the thorax will determine the presence of bruising, swelling over joints, splinting, signs of trauma, or an abnormal breathing pattern. Palpation and percussion are extremely important to localize and reproduce the pain because disturbances in the chest wall are the most common diagnoses in children with chest pain. Each rib cartilage should be palpated with only one finger or with the child's finger because palpation with 2 or more digits may cause splinting and will not recreate the pain. Reproduction of point tenderness at the origin of the spontaneous pain is the strongest evidence favoring the diagnosis of chest wall disease. Pain from the thoracic cage that can be elicited by movements of the torso or by flexion of the arms is highly suggestive of a musculoskeletal chest wall injury. The pain of costochondritis causes tenderness over the affected costochondral or costosternal junctions and can occur at rest or with movement. Adolescents with gynecomastia or breast pain may experience chest pain that is easily discernible on inspection and palpation of the developing breast tissue. No laboratory testing is

### BOX 133-1 Signs and Symptoms That Accompany Chest Pain and Warrant Referral or Hospitalization

#### SIGNS

- History of Kawasaki disease, Turner syndrome, Marfan syndrome, sickle cell disease, or cystic fibrosis
- Recent elective abortion, calf pain, oral contraceptive use
- Family history of hypertrophic obstructive cardiomyopathy or unexplained syncope
- Pica
- Foreign body aspiration
- Conversion disorder
- Cyanosis or toxic appearance
- Murmur that increases with Valsalva maneuver
- Pleural or pericardial friction rub
- Pulsus paradoxus
- Cardiac clicks, thrills, gallop, or third heart sound

#### SYMPTOMS

- Syncope
- Fevers, chills, weight loss, malaise, anorexia
- Respiratory distress
- Chest pain with exercise
- Palpitation or tachycardia

needed if any of these conditions is identified as a cause of the chest pain. Table 133-1 lists common, uncommon, and rare causes of chest pain and their associated signs and symptoms.

### Pulmonary Conditions

Children with asthma may have chest pain from excessive coughing and overuse of their intercostal muscles. Having pain alone as a manifestation of asthma is unusual for a child; usually, nocturnal cough, adventitious breath sounds, abnormal pulmonary function tests, or other signs of atopic diseases can exist.

A variety of other diseases of the airways, pleurae, and parenchyma can cause substernal or pleuritic chest pain. Pneumonia, asthma, exercise-induced bronchospasm, pleural effusions, and air in the pleural space can cause pain, but the chest pain is never the sole sign of the underlying disease process. A child with a parapneumonic effusion will classically have fever, tachypnea, tachycardia, a pleural friction rub or crackles (or both) on auscultation, and dullness to percussion in addition to the pleuritic chest pain that intensifies with inspiration.

Exercise-induced chest pain or chest tightness that resolves with the cessation of the exercise or the administration of bronchodilators may be a manifestation of cardiac disease but is more commonly related to exercise-induced bronchospasm. Exercise testing, cold air challenge, or a therapeutic trial of bronchodilators can confirm the diagnosis of exercise-induced

**Table 133-1** Common, Uncommon, and Rare Causes of Chest Pain and Associated Signs and Symptoms

CAUSE OF CHEST PAIN	SIGNS AND SYMPTOMS
<b>MUSCULOSKELETAL</b>	
Costochondritis (common)	Localized, superficial, reproducible pain over rib cartilage
Exercise, overuse, muscle strain (common)	Reproducible pain with use of involved muscle group
Protracted coughing or vomiting (common)	Intercostal muscle tenderness
Trauma	Localized pain; pain with movement of involved areas
Stitch (common)	Sharp, crampy costal pain that occurs with running
Precordial catch (uncommon)	Transient, stabbing pain at left sternal border; relieved by forced inspiration
<b>PULMONARY</b>	
Asthma (common)	Associated with cough, shortness of breath, wheezing, abnormal pulmonary function tests; relief with inhaled anti-inflammatory drugs or bronchodilators
Exercise-induced bronchospasm (common)	Abnormal exercise tests; improvement with bronchodilators
Pneumonia (common)	Crackles, fever, cough
Pleural effusion (uncommon)	Pleural rub, fever, decreased breath sounds
Pneumothorax (uncommon)	Sudden pain, referred shoulder pain, dyspnea, hyperresonance and/or absent or reduced breath sounds on affected side
Pulmonary embolus (rare)	Contraceptive use or recent abortion, pleuritic pain
<b>GASTROINTESTINAL</b>	
Esophagitis (common)	Retrosternal pain; relief with antacids
Gastroesophageal reflux (common)	Retrosternal burning pain; worse after eating and when reclining; relief with antacids
<b>CARDIAC</b>	
Hypertrophic cardiomyopathy (rare)	Syncope, family history, systolic ejection murmur
Pericarditis (rare)	Associated fever with acute onset of pain; pain increases with movement; narrow pulse pressure, distant heart sounds; alleviated by leaning forward
Myocarditis (rare)	Precedent viral illness, anorexia, shortness of breath, third heart sound or gallop, cardiomegaly
<b>NONORGANIC</b>	
Psychogenic (common)	Normal physical examination, trouble sleeping, family or school problems, life stresses, family history of chest pain, other somatic complaints
Hyperventilation (common)	Associated light-headedness, paresthesias, underlying anxiety

or cold air-induced bronchospasm. Treatment with bronchodilators will help these children participate in sports and allow them to lead normal, active lives.

Spontaneous pneumothorax can occur in teenagers with chronic illnesses such as cystic fibrosis, asthma, and Marfan syndrome, but it can also occur in healthy teenagers. A child with cystic fibrosis who experiences chest pain should be assumed to have a pneumothorax until proven otherwise. Dyspnea, shoulder pain, and tachypnea are often observed in addition to the chest pain in a typically tall, thin adolescent who develops a spontaneous pneumothorax.

### Gastrointestinal Conditions

Acid reflux to the esophagus can mimic the pain of angina and can cause both acute and chronic chest pain. Pain that originates from the esophagus or stomach is described as an uncomfortable, gnawing substernal burning sensation. The pain can last for hours, and it intensifies after meals and on reclining. Any inflammation of the esophagus, abnormalities of peristalsis, esophageal foreign body, or trauma can cause

chest pain. The most common gastrointestinal cause of chest pain is esophagitis. However, because the clinical presentation of esophagitis can be nonspecific, children with idiopathic chest pain may benefit from a trial of antacids or H<sub>2</sub>-receptor antagonists before embarking on an exhaustive evaluation.

### Cardiac Conditions

The least likely but most worrisome causes of chest pain in children are cardiac disorders that cause myocardial ischemia. Cardiac disease in children rarely produces isolated chest pain and is always associated with other findings at evaluation. Sudden death from cardiac disease in children is caused by a small subgroup of disorders: abnormalities of the myocardium or coronary vessels, specific congenital heart lesions, arrhythmias, and conduction disorders. Signs and symptoms that identify children with these disorders and warrant cardiology evaluation include exertional nonrespiratory dyspnea, syncope, and palpitations. A pediatric cardiologist should also see children with chest pain and a family history of sudden death.

A child with chest pain from myocarditis or pericarditis usually appears ill, with fever, dyspnea, changes in the pain associated with the respiratory cycle, and abnormal auscultatory findings. In most instances, the echoviruses, especially coxsackievirus B, are identified as the culprit responsible for myocarditis. Pericarditis can result from either an infectious agent or an autoimmune process.

Aortic stenosis and idiopathic hypertrophic cardiomyopathy, which are the most important lesions that cause left ventricular outflow obstruction, can cause chest pain as a result of the heart's inability to increase the cardiac output with exercise. These disorders cause syncope and chest pain with exertion. Mild aortic stenosis does not cause chest pain.

Chest pain may be, but is not usually, the primary complaint of children with arrhythmias unless they perceive the palpitations as painful. More commonly, older children complain of light-headedness or dizziness along with the palpitations. The arrhythmia can usually be detected on auscultation and confirmed by resting electrocardiogram. If the palpitations or chest pain occur infrequently or are not associated with exercise, then referral to a pediatric cardiologist is indicated for Holter monitoring.

Although mitral valve prolapse (MVP) is commonly thought to cause chest pain in adolescents, most children with MVP are asymptomatic. Chest pain has been found to be no more common in teenagers with MVP than it is in those without MVP.

Findings on auscultation that point to a cardiac source of pain include clicks, rubs, and systolic murmurs. A murmur can be worrisome if it increases in intensity with the Valsalva maneuver or any other procedure that expands the degree of left ventricular outlet obstruction. A third heart sound or gallop is heard in myocarditis and congestive heart failure. Pleural friction rubs, wheezes, tachypnea, and crackles suggest a pulmonary cause. Conversely, hyperventilation associated with light-headedness, paresthesias, dizziness, and a high level of stress or anxiety suggests a hyperventilation syndrome.

### Idiopathic Causes

Especially among adolescents, as many as 39% of patients complaining of chest pain will not have a readily identifiable cause. Children with chronic chest pain, no history of respiratory or cardiac disease, and a normal physical examination are unlikely to have a serious cause for their pain. For teenagers, a careful explanation of the pathophysiologic features in concrete terms is a fundamental part of their therapeutic regimen. Several studies of children with idiopathic chest pain have shown that most of them have no further pain 1 to 2 years after their initial evaluation.

### Psychogenic Chest Pain

A child with a long history of chest pain, other recurrent somatic problems, school or sleep problems, a family history of chest pain, or any combination of these factors may have a psychogenic cause for the pain. If a psychogenic cause is entertained, then the

diagnosis should not be made by exclusion of organic disease; rather, the diagnosis should be based on positive psychiatric evidence. As with any somatic illness, if the family or the child is able to articulate a relationship between the chest pain and stress or emotional upheaval, then the diagnosis will be easier for them to comprehend and accept. Emotional causes for chest pain seem to be more common in adolescents than in children younger than 12 years. Hyperventilation can be associated with the chest wall syndrome but is more commonly seen in teenagers with underlying anxiety. The diagnosis is usually made by history alone because the child may need to hyperventilate for 20 minutes to reproduce the pain.

Almost all children with hyperventilation syndrome have associated paresthesias, carpopedal spasm, and light-headedness. For a child with an acute episode of hyperventilation, the treatment is to have the child breathe into a paper bag to relieve the hypocapnia. Resolution of the chronic problem is based on techniques to allow the children to understand the nature of their anxiety and allow them to regain control of their emotional state. The treatment of other forms of psychogenic chest pain should be focused on the family's comprehension of the cause of the pain and reassurance that no long-term sequelae exist, all while acknowledging that the pain is real. For children with more significant psychiatric problems, referral to a psychiatrist may be necessary.

### When to Admit

Rarely will a child with chest pain need to be hospitalized because, for the most part, chest pain is usually benign, self-limited, and not associated with severe intrathoracic illness. Box 133-1 provides guidance for when to refer and when to admit. However, children with the following should be hospitalized:

- Myocarditis
- Pericarditis
- Empyema
- Pneumothorax
- Significant thoracic trauma
- Acute chest syndrome
- Esophageal foreign bodies
- Coronary artery anomalies or other cardiac lesions
- Myocardial ischemia
- Chest pain and palpitations
- Cyanosis
- Distress

### SUGGESTED READINGS

Thull-Freedman J. Of 3700 children thought to have non-cardiac chest pain at initial paediatric cardiology clinic evaluation, none suffered cardiac death over a median of 4 years follow-up. *Evid Based Med.* 2012;17(6): 190-191

## Chapter 134

# CONSTIPATION

Peter F. Belamarich, MD

The term *constipation*, which denotes both a symptom and a chronic condition, refers to the infrequent elimination of large or hard stools that may cause pain on defecation. In childhood, constipation that is not caused by another condition is known as idiopathic or functional constipation. Given that constipation encompasses both objective and subjective complaints that vary by age, it has defied a comprehensive standard definition. Several consensus groups have developed definitions of constipation; however, none of these definitions seems entirely satisfactory to all. One expert consensus definition of constipation is presented in Box 134-1.

Constipation is a common symptom among children in the industrialized world. In parental surveys, 16% to 37% of toddlers are reported to suffer from it. Functional constipation presents a challenge to the pediatrician, as suggested by the observation that the evaluation and treatment of constipation occupies 25% of all referrals to pediatric gastroenterologic services, although these children rarely require an invasive procedure. To pediatricians caring for chronically constipated children, treatment failure raises the question of Hirschsprung disease. Among referral populations, more than 90% of childhood constipation is functional; ultimately, 50% to 90% of these children are cured.

The approach to constipated children used by gastroenterologists is well within the scope of the primary care pediatric practice. The focus of this chapter is on identifying and treating children who have functional constipation. An evidence-based guideline, endorsed by the American Academy of Pediatrics, has been published on evaluating and treating constipation.

### BOX 134-1 Definition of Constipation

Constipation is a symptom defined by the occurrence of any of the following, independent of stool frequency:

- Passage of hard, scybalous, pebble-like, or cylindrical cracked stools
- Straining or painful defecation
- Passage of large stools that may clog the toilet
- Stool frequency less than 3 per week, unless the child is breastfed

Adapted from Hyams J, Colletti R, Faure C, et al. Functional gastrointestinal disorders: Working Group Report of the First World Congress of Pediatric Gastroenterology, Hepatology, and Nutrition. *J Pediatr Gastroenterol Nutr.* 2002;35 (Suppl 2):S110.

## PATHOPHYSIOLOGIC MECHANISM OF FUNCTIONAL CONSTIPATION

### Normal Colonic Function

The role of the colon is to reclaim water from the liquid ileal effluent. This task is accomplished, in part, by a motility pattern that includes focal circular contractions, which impede the progress of the luminal contents while solutes and water are absorbed. Subsequently, forward progress of the relatively dehydrated fecal stream is achieved by coordinated contractile waves, which propel the bolus of stool to the next colonic segment and ultimately to the rectum. The final elimination of stool is controlled by defecation, a coordinated sequence of neuromuscular events with both reflexive and conscious components. Control of defecation, continence, is a critically important social achievement in early childhood. At rest, continence is maintained by the involuntary resting tonic contraction of the smooth muscle cuff of the internal anal sphincter and by the posterior turn of the anal canal in relation to the anterior angulation of the rectal vault. This angle is modulated by the puborectalis sling muscle, which loops posteriorly around the anorectal junction and is anchored anteriorly on the pubic bone.

When stool arrives in the rectal ampulla, causing distention of the rectal walls, a reflexive relaxation of the internal anal sphincter occurs, which lowers the pressure of the anal canal and allows the stool bolus to descend to the anal canal, a phenomenon known as the rectoanal inhibitory reflex. Control of defecation then occurs by the voluntary (and learned) deliberate contraction of the striated muscle of the external sphincter and puborectalis sling muscles, which increase the pressure in the anal canal and make the exiting angle more acute. Conversely, a Valsalva maneuver, in combination with relaxation of the external anal sphincter and the puborectalis sling, permits defecation to proceed. Normal stool frequency decreases from about 4 stools per day in infancy to 1.2 stools per day at 4 years old.

### Factors in Functional Constipation

The pathophysiologic basis of functional constipation is not clear. It may be the final common pathway for a number of underlying distinct conditions: a disorder of the dynamics of defecation; a problem with rectal sensation; or a disorder of colonic transit, leading to impacted, overly desiccated stool in the colon. Functional constipation can also arise solely from a behavioral aversion to or learned problems with the process of defecation.

Stool withholding, the act of voluntarily deferring defecation to avoid pain, significantly contributes to the chronicity of constipation in childhood independently of the primary cause.

### Stool Withholding

In practical terms, several commonly recognized clinical scenarios can result in constipation, including painful anal fissures, perianal streptococcal cellulitis,

traumatic toilet-training experiences, and transient periods of dehydration, illness, or immobility. Stool withholding likely figures prominently in the perpetuation of constipation when pain or an aversive experience is the primary insult. Withholding behavior in the toddler or child is strongly self-reinforcing. The child is avoiding painful bowel movements, which makes the stool harder and more painful to pass. Parents who focus with great concern on the withholding crisis, often believing that the child is valiantly trying to defecate rather than to withhold, also reinforce stool withholding unwittingly. Toddlers love the worried attention of their parents! The lack of privacy commonly found in some school lavatories can engender withholding by older children. Anorectal manometric studies have documented abnormalities in the dynamics of defecation in a large series of chronically constipated children, the most common being a paradoxical contraction of the external anal sphincter and the puborectalis sling in response to the rectoanal inhibitory reflex.

This commonly identified abnormality is known variously as rectoanal pelvic floor dyssynergia, abnormal defecation dynamics, and anismus. Most experts consider dyssynergia a learned phenomenon. For a large proportion of chronically constipated children, painful defecation and withholding antedate the clinical presentation of constipation by 1 to 5 years. In a significant subset of children who experience persistent constipation, withholding becomes entrenched and particularly difficult to unlearn. In fact, initial enthusiasm over manometrically based biofeedback training was based on its potential to help patients identify and unlearn this withholding behavior. However, controlled studies have not documented greater improvements in the outcome for patients who have undergone biofeedback training than for those given a standard treatment regimen.

### Sensory Abnormalities

Another common manometric abnormality found in chronically constipated children is known as megarectum. As the name implies, the rectum is dilated with a chronic impaction, a finding associated with an increase in the sensory threshold to minimal rectal distention, as well as an increase in the minimal volume required to initiate the urge to defecate. These sensory abnormalities persist for several years in some patients after successful treatment, suggesting that ongoing sensory abnormalities contribute to relapses and perhaps to the initial pathogenesis of constipation in some children.

### Slow Transit

Constipation from abnormally slow transit of the fecal stream through the colon occurs predominantly in young women but can occur in children. Whether slowed colonic transit is the primary problem or is secondary to distal difficulties with defecation is unclear. Slow-transit constipation in children is not easily differentiated clinically from normal-transit constipation. A unique therapeutic approach to slow-transit constipation has not emerged.

### Dietary Factors

Whether dietary factors alone cause constipation is unclear. In infancy, human milk is highly protective. Despite broad agreement that dietary fiber has an important role in promoting a regular bowel habit, very little literature and no prospective studies support this belief. A case-control study has documented decreased fiber intake as a risk factor for childhood constipation; however, substantial overlap exists in the fiber intake between cases and controls. Nonetheless, many physicians have remarked that, in infancy, the transition from human milk or formula to whole cow's milk, or periods of excess protein intake such as occur in toddlers with excessive whole cow's milk consumption, are associated with constipation. The tenacious and harmful myth that iron-containing formula causes constipation has been disproved many times.

### DIFFERENTIAL DIAGNOSIS

The differential diagnosis of chronic childhood constipation includes many conditions (Box 134-2). Despite the large number of possible diagnoses, at least 90% of affected children have functional constipation.

Frequently, the foremost consideration in the differential diagnosis of chronic constipation is Hirschsprung disease. The most common basis for this concern is treatment failure, an appropriate concern in early infancy when functional constipation is unusual and easily treatable. However, treatment failure in the toddler and the school-aged child more often reflects the complexity and duration of intervention required to treat functional constipation adequately than a missed diagnosis of Hirschsprung disease. Fortunately, several findings in the history are useful in the process of ruling out Hirschsprung disease. Perhaps most useful is that almost all children with functional constipation withhold stool in response to the rectoanal inhibitory reflex, whereas this reflex is absent with Hirschsprung disease. Simply stated, stool withholding behaviors are a historical finding that almost always rule out Hirschsprung disease. Conversely, Hirschsprung disease should be considered in any child with refractory constipation who has had any of the following:

1. Failure to pass meconium in the first 24 hours of life.
2. Onset of constipation before 3 months of age.
3. Symptoms of intestinal obstruction at any time (distention, emesis).
4. Lifelong dependence on laxatives, enemas, or mechanical manipulation to initiate defecation.
5. History of enterocolitis in early infancy (sometimes misdiagnosed as gastroenteritis).
6. Constipation in children with syndromes associated with Hirschsprung disease (eg, trisomy 21, Waardenburg-Shah, congenital central hypoventilation).
7. Failure to thrive or growth faltering. See Table 134-1 for a summary of features that distinguish Hirschsprung disease from functional constipation.

Other conditions that specifically affect the neuromuscular function of the colon include the

**BOX 134-2 Differential Diagnosis of Constipation in Childhood****FUNCTIONAL CONSTIPATION**

- Disorders of intestinal neuromuscular function

**ANAL AND RECTAL DISORDERS**

- Anal fissure
- Anterior ectopic anus
- Anal stenosis
- Anorectal malformations
- Rectal duplication
- Anal trauma (abuse)
- Pelvic tumor (presacral teratoma, ganglioneuroma, ovarian cyst, hemocolpos)

**NEUROLOGIC—NEUROMUSCULAR**

- Hirschsprung disease
- Pseudoobstruction syndromes
- Spinal cord lesions
- Spinal dysraphism, including spina bifida
- Cerebral palsy
- Neuromuscular diseases with hypotonia

**METABOLIC AND ENDOCRINE**

- Hypothyroidism
- Diabetes insipidus

- Hypercalcemia

- Hypokalemia

**MEDICATION AND TOXIN RELATED**

- Antihistamines
- Anticholinergics
- Anticonvulsants
- Opioids
- Bismuth, aluminum hydroxide
- Tricyclic antidepressants
- Iron preparations (not iron-fortified formulas)
- Plumbism
- Infant botulism

**MISCELLANEOUS**

- Celiac disease
- Cystic fibrosis
- Cow milk allergy
- Scleroderma
- Systemic lupus erythematosus

**Table 134-1 Comparison of Hirschsprung Disease to Functional Constipation**

CHARACTERISTIC	HIRSCHSPRUNG DISEASE	FUNCTIONAL CONSTIPATION
Prevalence	~1 in 6,000 births	1.5% of 7-year-old boys
Failure to pass meconium <24 hr	58%–94%	~5%
Constipation in first 3 mo	90%	Rare
Symptoms or signs of obstruction	Common	Absent
Abdominal distention	Common	Mild or absent
Stool size	Narrow, ribbon-like	Intermittent large-caliber stools
General appearance	Chronically ill	Well
Stool-withholding behavior	Rare	Extremely common
Soiling	Unusual	Common
Stool in ampulla	Unusual	Common
Plain radiographs	Empty rectum	Dilated enlarged rectum
Rectal manometry	Rectoanal reflex absent	Rectoanal reflex present
Typical barium enema	Distal spasm, proximal dilatation	Diffusely dilated colon and rectum

pseudoobstruction syndromes, which are characterized by intermittent episodes of functional intestinal obstruction. Furthermore, a large percentage of children who have generalized neuromuscular disabilities (eg, cerebral palsy, muscular dystrophy, generalized hypotonia) have refractory constipation that is frequently multifactorial and difficult to treat.

Anorectal disorders producing constipation include anal fissures, anal stenosis, anterior ectopic anus, and extrinsic masses that partially obstruct the rectum. Fissures may induce a self-perpetuating cycle of

withholding and worsening of constipation that causes reinjury. Congenital anal stenosis is characterized by straining during the production of small-caliber stools; it is frequently diagnosed during infancy. The anal canal is noted to be narrow and not distensible during digital examination. Occasionally, chronic constipation is caused by a subtle anorectal malformation known as anterior ectopic anus, in which the anal orifice is misplaced anteriorly so that the stool bolus must turn anteriorly at the perineum to exit. The parents may report seeing a perineal bulge

when the infant attempts to defecate. Surgical reconstruction may be necessary in children who fail to improve with medical therapy. In rare cases, constipation is a manifestation of an intermittent or partial extrinsic obstruction of the rectum by a rectal duplication cyst or by a pelvic mass such as a neuroblastoma, presacral teratoma, or ovarian tumor.

Spinal cord lesions affecting the second, third, and fourth sacral nerves are associated with both sensory and motor deficits affecting defecation. Trauma to the sacral cord, intraspinal and extraspinal tumors, and congenital malformations that can alter the spinal cord function should be suspected when constipation is accompanied by abnormalities in bladder function or gait, or when there are visible abnormalities or palpable findings over the lumbosacral spine, including hair tufts, dimples, pigmentary abnormalities, or a deviated gluteal cleft.

Metabolic and endocrine disorders associated with constipation include hypothyroidism, hypercalcemia, diabetes insipidus, hypokalemia, and plumbism. These conditions generally do not manifest with chronic constipation as a sole symptom.

Both cystic fibrosis and celiac disease can cause constipation. Physicians should be alert to these possibilities in children with poor growth in weight or height, recurrent respiratory complaints, anemia, or hypoproteinemia.

Many medications and toxins are reported to cause constipation (see Box 134-2).

Recently, 2 reports have linked constipation to cow milk protein allergy. In a study of a referral population of 65 children who had treatment-resistant chronic constipation, 44 had a positive therapeutic response to the substitution of soy milk for cow milk. Questions remain, however, about the generalizability of these findings to the primary care setting.

Box 134-3 presents a diagnostic approach for children thought to have an organic cause of their constipation.

## COMMON PRESENTATIONS OF FUNCTIONAL CONSTIPATION

### Infancy

Particularly in the first 6 months of life, parental notions of what constitutes constipation may be incorrect. Breastfed infants may have a mushy stool as infrequently as once a week. In the otherwise healthy infant, this situation does not deserve the label constipation and requires no intervention. In general, stool consistency rather than frequency is the critical determinant of constipation in the infant. Parents also worry about infants who strain or grunt excessively (often turning deep red) in the course of producing a soft stool of normal caliber. Manometric studies have documented the presence of a functioning rectoanal inhibitory reflex at birth, and infants exhibiting this behavior are likely attempting, unsuccessfully, to coordinate the voluntary with the involuntary components of defecation.

The truly constipated infant, who does require treatment, typically displays a pattern of straining associated with either the production of a desiccated

### BOX 134-3 Studies in Children With Constipation

- For growth failure, failure to thrive, short stature
  - Thyroid function tests
  - Celiac panel

  - Hirschsprung disease
- For delayed passage of meconium
  - Anorectal manometry
  - Rectal suction biopsy
  - Unprepared contrast enema
  - Sweat test
- For hair tufts, lipomas or hemangiomas overlying the lumbosacral spine and for abnormalities of gait, urination, absence of anal wink or cremaster reflex
  - Consider imaging the lumbosacral spinal cord (ultrasound, magnetic resonance imaging)
- For refractory constipation
  - Thyroid function tests
  - Serum calcium
  - Potassium
  - Lead
  - Celiac panel
  - Sweat test

Routine studies of children who are thought to have functional constipation are not recommended.

plug of stool followed by loose stool or by the production of a consistently desiccated stool that has a pebbly consistency.

### Toddlers

Although parents of toddlers are usually aware of when their child is constipated, they frequently do not recognize stool withholding. During the act of withholding, the child may hide quietly, clinging to an inanimate object, while squeezing the buttocks together. Numerous variations of stool-withholding behavior exist, including crouching, dancing or walking on tip-toes, and crying out in anticipation of the pain. Not infrequently, these episodes are misinterpreted by the parents as valiant attempts to defecate, and they generate great concern. Eliciting a history of stool withholding is critical for both diagnostic and therapeutic purposes.

### Childhood

Once the child has attained privacy in the bathroom, parents are not likely to be involved in the toilet routine, and constipation becomes occult. The child often goes to the bathroom with a regular or increased frequency but during defecation passes only a small, hard piece of desiccated stool. Not infrequently, the child emerges from the bathroom not terribly bothered. The parent inquires, "Did you go?" The child answers, "Yes." Thus both parties are happy. This stooling pattern, known as incomplete evacuation, is

**BOX 134-4 Findings That Support the Diagnosis of Functional Constipation**

- Onset after infancy
- Presence of stool-withholding behavior
- Absence of red flags
- Episodic passage of large-caliber stools

common in school-age children and is punctuated episodically by the passage of massive bowel movements. Many children do not seem very bothered by their constipation and are brought in by their parents not for the constipation itself but rather for associated phenomena, such as soiling, recurrent abdominal pain, blood streaks seen on the stool, excessive flatus, or anorexia. Finally, pelvic floor dyssynergia seen in children with stool withholding can affect urinary voiding dynamics, predisposing some to enuresis or urinary tract infection. Box 134-4 lists features that support the diagnosis of functional constipation.

**EVALUATION**

Functional constipation frequently can be diagnosed by history, physical examination, and therapeutic response to a comprehensive treatment regimen. The history should incorporate the frequency, consistency, and caliber of the stools that the child passes, as well as the age of the child at the onset of constipation. The newborn history should specifically establish whether the child passed meconium in the first day of life. A history of the child's toilet-training experience and whether traumatic toileting experiences occurred is critical in toddlers and preschool-aged children. The diet history can establish whether the onset of constipation occurred concurrently with the transition to cow milk or with periods of high protein intake (excessive cow whole milk consumption).

Common complications of constipation should be assessed: fissures, bleeding, abdominal pain, anorexia, enuresis, and urinary tract infection. A history of distention and vomiting is explored because they are not caused by functional constipation. Eliciting a history suggesting stool withholding is critical because it strongly supports the diagnosis of functional constipation and should be addressed in the therapeutic plan. Details of prior evaluations and treatments should be explored, including over-the-counter medicines, home remedies, alternative therapies, and culturally specific therapies that can be incorporated in the treatment plan, if they pose no harm.

Specific questions should address the differential diagnosis. Symptoms of Hirschsprung disease, as well as endocrine, metabolic, and neurologic disease, should be sought. The possibility of an occult spinal process affecting the sacral nerves can be addressed by inquiring about any changes in the urinary voiding

pattern (urinary stream or urinary continence) or in the child's gait. The family history covers heritable conditions in the differential diagnosis and a family history of functional constipation, which has been shown to have a heritable component. A developmental history may also be important.

On physical examination, the child's growth parameters, including recent growth velocity, should be normal. The child should appear well and not wasted or malnourished. The abdomen should not be distended, and the examination should establish the presence or absence of a fecal impaction in the lower quadrants or in the hypogastric area. The external examination of the perineal area is performed to establish normal placement of the anal orifice and to look for evidence of soiling, fissures, skin tags, and a normal anal wink in response to touch.

When a rectal examination can be done with the child's cooperation, it should be part of the evaluation. In most children who have functional constipation, desiccated stool is found in the rectal vault on rectal examination. For older children who have long-standing constipation and a megarectum, chronic rectal distention may efface the internal sphincter along the rectal wall, making the anal canal feel foreshortened. Children who soil from chronic constipation with a megarectum have only a sensory disorder; thus, the tone of the internal sphincter should be normal. The examiner should be alert during the digital examination for the rare situation in which an extrinsic mass is compressing the rectum. A patulous anus is indicative of a neurologic lesion or of sexual abuse involving the anus. Especially in infants, an empty rectum on digital examination raises the possibility of Hirschsprung disease, particularly in conjunction with an explosive gush of stool on withdrawal or a hard, impacted mass palpated in the pelvis or lower abdomen. Impactions in infancy are unusual and may indicate Hirschsprung disease. In the older child who has functional constipation, an empty rectum may be found occasionally if the child has just defecated. Nonetheless, the possibility of Hirschsprung disease should be considered carefully.

The evaluation should continue with an examination of the spine, looking for a dimple, hair tuft, or palpable vertebral deformity (signs of spina bifida occulta), and from this evaluation to a thorough neurologic examination that explicitly assesses the tone, strength, symmetry, and reflexes of the lower extremities and to an analysis of the patient's gait.

Routine laboratory tests are not indicated in evaluating for functional constipation. In addition, a recent systematic review has shown that plain abdominal radiographs do not have significant diagnostic value. Nonetheless, plain radiographs of the abdomen can be used selectively for confirmation that an abdominal mass appreciated on physical examination is indeed a fecal impaction.

Children thought to have Hirschsprung disease should be discussed with a consulting surgeon and radiologist to decide on the choice of initial diagnostic testing, keeping in mind that rectal biopsy is the gold standard. Box 134-5 presents red flags in constipation.

**BOX 134-5 Red Flags in Childhood Constipation**

- Failure to thrive, weight loss, poor growth
- Vomiting
- Abdominal distention
- Persistent anal fissures, perianal disease
- Persistent blood in stool or guaiac-positive stool
- Delayed passage of meconium
- Weak urinary stream, diurnal enuresis

**TREATMENT**

Treatment of constipation involves laxatives, parental education, diet, and behavioral modification. Consideration must be given to the age of the patient and the duration of symptoms. Whereas transient constipation of several days' duration typically can be managed with 1 to a few days of laxative use and dietary change, most patients who have functional constipation are affected for weeks to months before coming to attention and require a phased approach and months of treatment. Successful treatment of functional constipation in older children may even require 1 to 2 years of laxative therapy. Ultimately, the goals of treatment are to establish a pattern of soft bowel movements at a regular frequency (at least 3 per week), to wean the child from pharmacotherapy, and to have the child and family manage the problem on their own with diet and behavioral modification.

**Treatment of Infants**

Before they are introduced to infant food, constipated infants can be treated by the addition to the diet of undigestible, osmotically active carbohydrates: either dark corn syrup or malt soup extract can be added to the formula in a dose of 2 to 6 teaspoons divided in several bottles per day. Once juice and infant food are introduced, apple or prune juice and fruits can be added to the diet. Infant glycerin suppositories can be used at the beginning of therapy to remove a desiccated rectal plug but should not be the mainstay of therapy because infants can become behaviorally conditioned to depend on rectal stimulation to initiate defecation. Infants should not receive mineral oil because of the risk for pneumonia from aspiration. Externally visible anal fissures should be treated with petroleum jelly. Two studies have established the efficacy of polyethylene glycol (PEG) in infants. Infants whose constipation is refractory to these measures should be referred to a pediatric gastroenterologist.

**Treatment in Toddlers and Older Children**

The treatment of established constipation is divided into 3 phases: (1) education and disimpaction, (2) maintenance, and (3) weaning. This method has been adopted widely by pediatric gastroenterologists and advocated in published guidelines.

**Education**

The treatment of constipation begins with parental education regarding the pathogenesis of constipation. Particular focus is given to the concept that, once established, constipation frequently engenders withholding, which is self-perpetuating. Toddlers, in particular, require several months of laxative treatment that produces soft stools before they abandon this behavior. Parents should be instructed to ignore stool withholding events as they would a temper tantrum. At times when the child is not withholding, parents should talk directly to toddlers and engage them in the therapeutic program: "I want you to push the poo-poo out of your body; don't hold it in. That's how you will get better, and it will stop hurting!"

Physicians should address the widely held misconceptions that long-term laxative use in childhood is not safe or engenders laxative dependence. This fear, compounded by a general reluctance to medicate children for what is widely perceived as a transient problem, almost always leads to premature discontinuation of therapy. In fact, innumerable studies have established that nonstimulant laxatives such as mineral oil, milk of magnesia, PEG, and lactulose do not result in dependence. On the other hand, experts discourage the prolonged use of stimulant laxatives (Senna, Bisacodyl), but the limited use of Senna, an anthraquinone-stimulant laxative, is acceptable.

**Disimpaction**

Treatment begins with disimpaction in the toddler or child who has had months to years of symptoms or an impaction on examination. For children attending school, disimpaction treatment (Table 134-2) should be deferred until the weekend; in the interim, the child can be treated with mineral oil to lubricate the impacted stool. Enemas once a day for 3 to 6 days are simple and effective and, with some important caveats, are safe. Dose guidelines should be followed, and the child should be brought to medical attention in the rare event of failure to stool following an enema. Sodium phosphate enemas are contraindicated in children who weigh less than 10 kg, in those who have any cardiac or renal impairment or electrolyte disorders, and in those who may have any form of intestinal obstruction. In 4- to 11-year-old children, a comparison of daily oral PEG for 6 days versus daily enemas for 6 days showed equal efficacy in resolving fecal impactions. The choice of enemas versus the oral route should be made with the child and family's input.

The goal of disimpaction is to remove all the hard-formed stools throughout the colon. A follow-up telephone call after 2 to 3 days can ascertain whether the child is still passing hard stools. Any questions about whether the disimpaction phase of treatment is complete should prompt a revisit for an abdominal and rectal examination or an abdominal radiograph. Last, children who have extremely hard or treatment-resistant impactions can be admitted for nasogastric administration of a PEG solution or surgical disimpaction. Failure to achieve a thorough disimpaction, a

common therapeutic mistake, undermines successful treatment because laxatives given in maintenance doses do not penetrate or remove the impaction. For the same reason, fiber is withheld during the disimpaction phase of treatment.

**Maintenance**

The maintenance phase of treatment follows disimpaction and should incorporate laxative use and dietary and behavioral advice. Maintenance doses of laxatives are listed in Table 134-2. Telephone follow-up within 2 to 3 days of starting therapy is essential so that the laxative can be titrated to a dose that induces a daily soft bowel movement. Results of a Cochrane review support both PEG and mineral oil as superior to other agents for the treatment of constipation. If mineral oil is used, then it should not be prescribed to children younger than 2 years or to children who are at risk for pulmonary aspiration. PEG has gained wide use for the treatment of functional constipation. PEG, an osmotic laxative, is a polymer of ethylene glycol that is not absorbed or fermented by colonic bacteria. One appeal of PEG is that it is a fairly tasteless, water-soluble powder that can be disguised when mixed into a child's drink. Pediatric studies of PEG have established clinical tolerance, effective dose, and the absence of unanticipated or serious adverse effects in small groups of study subjects.

A recent systematic review of nonpharmacologic therapies for childhood constipation concluded that apart from an increase in fiber intake, other therapies such as an increase in fluid intake, the addition of probiotics/prebiotics to the diet, an increase in physical activity, and yoga are not studied to the point at which they can be offered as evidence-based recommendations. These therapies deserve further study because they may be beneficial and are associated

with little harm. The addition of dietary fiber is a widely advocated adjunct to the treatment of childhood constipation, and a recent randomized controlled trial has shown benefits of a fiber supplement when prescribed with a laxative. Alternatively, dietary changes that increase the child's fiber intake can be made and include the introduction of whole-grain breads and cereals and increasing the child's fruit and vegetable intake.

Simple behavioral advice has been a mainstay of treatment recommendations. For toddlers, the focus is on replacing stool-withholding behavior with deliberate attempts to defecate. Toilet-training efforts are deferred until the child stops withholding. For older children, a behavioral modification program of sitting on the toilet for 5 to 10 minutes after meals to capitalize on the gastrocolic reflex is recommended, with success rewarded by the use of a star-chart system: the child should be rewarded for the targeted behavior (sitting). The physician is responsible for titrating the laxative dose to achieve the desired effect (a soft bowel movement every day), which requires an active partnership with the child and parents, who need to report to the physician frequently. Referral to a child behavior specialist or psychiatrist is warranted when toileting is the focus of a power struggle or when a significant mental health problem complicates the treatment regimen.

**Weaning From Maintenance Therapy**

Weaning, as opposed to abrupt cessation, of laxative therapy is the next phase of treatment. Successful weaning can occur following 6 to 12 weeks of maintenance treatment in some toddlers but may not be possible for 6 to 12 months in older children. Typically, the daily laxative dose is decreased to 75%, 50%, and 25% of the initial dose over successive months, or the full dose is given every second day for

### BOX 134-6 Common Reasons for Treatment Failure of Functional Constipation

- Reliance on dietary advice alone
- Inadequate disimpaction
- Failure to escalate laxative dose to achieve 1 to 2 soft stools per day
- Failure to address widely held notion that laxatives are addictive, leading to premature discontinuation
- Relying on dietary fiber alone

6 to 8 weeks and then every third day for another 6 to 8 weeks. Efforts to increase the child's fiber intake and to comply with the behavioral program are redoubled during weaning. Older school-aged children are encouraged to practice self-monitoring of the frequency and adequacy of their bowel movements, and a rescue plan for an enema, a suppository, or a dose of stimulant laxative must be in place for a transient relapse (no stool for longer than 3 days) that may occur during weaning. The inability to wean from laxatives after 12 months of therapy is not uncommon in functional constipation but may reasonably justify referral to a pediatric gastroenterologist. Box 134-6 presents common reasons for treatment failure of functional constipation. Remaining optimistic and involved at this point is important because improvement beyond 12 months of therapy is well documented.

#### WHEN TO REFER

- Abnormal studies
- Findings that are inconsistent with functional constipation (growth failure, distention, vomiting, bleeding)
- Significant behavioral, emotional, and parenting problems complicating treatment
- Refractory to comprehensive treatment regimen

#### WHEN TO ADMIT

- Constipation associated with obstruction or enterocolitis
- Failure of disimpaction as an outpatient

## Chapter 135 COUGH

Michael G. Marcus, MD

### INTRODUCTION

Cough is among the most common complaints of children. Although generally resulting from acute viral infections and therefore self-limited, cough may be the harbinger of a more serious problem. Because cough can be exceedingly disruptive to the child and family, it can lead to significant anxiety for all involved parties. Allaying this anxiety through appropriate diagnosis and management is of prime importance to the primary care physician.

### PATHOPHYSIOLOGIC FEATURES

Cough can be described as a forceful exhalation. Its primary purpose is to facilitate the removal of inhaled irritants and secretions from the airway. The cough reflex can be triggered by stimulation of the cough receptors located at all levels of the respiratory tract, beginning at the sinus level and extending caudally throughout the respiratory tree and ending at the terminal bronchi. It also includes the auricular branch of the vagus nerve (Arnold nerve), which carries afferent impulses from the concha of the ear and posterior portion of the external auditory canal. Impulses from

these cough receptors travel through the cranial nerve afferent pathway to the medullary cough center. The reflexive efferent response of this activation causes the coordinated activity of glottic closure and diaphragmatic, chest wall, abdominal, and pelvic floor contraction, resulting in cough.

The cough sequence can be divided into 3 classic phases. The first phase, termed the inspiratory phase, results in a deep inspiration ending in glottic closure. During the short second phase, termed the compressive phase, intrathoracic pressure increases as a result of coordinated contraction of the expiratory muscles. With the expiratory third phase, the glottis opens rapidly, leading to the sudden, sometimes explosive, release of the pent-up intrathoracic air (ie, cough). Coupled with this third phase, secretions and irritants are expelled from the airway. Incomplete or inefficient removal of these materials will result in recurrence of the cough sequence, as will ongoing irritation or inflammation.

## CLASSIFICATION

Many classification schemes for cough have been developed over the years, and each has its benefits and limitations. Ultimately, any useful classification scheme must help in planning an efficient and successful evaluation and management plan. When classifying cough, 2 basic questions need to be addressed. First is whether the cough is acute or chronic (>4 weeks' duration), with chronic cough likely requiring a more extensive evaluation plan. The second question is whether the cough is triggered by upper, lower, or combined airway pathology (although the effect of the upper airway on the etiology of cough is somewhat controversial), and whether it is specific or nonspecific. This is not always apparent, especially in younger children, but is critical to determine to minimize unnecessary testing, treatment, or both.

## DIFFERENTIAL DIAGNOSIS

In considering a functional differential diagnosis, the physician should try to answer the above 2 questions on the initial assessment. In this regard, the character of the cough can sometimes be helpful, with *croupy*, *throaty*, and *honking (foghorn)* coughs being more likely to originate in the upper airway. However, young children with asthma (clearly a disease of the lower airways) may initially exhibit a croupy cough, presumably from the physiologic narrowing of the subglottic space in children younger than 4 years.

At the other extreme, although a productive cough with expectoration of sputum is classically associated with lower airway inflammation (eg, pneumonia, asthma), children with severe chronic sinusitis (a disease of the upper airway) will often cough and expectorate or swallow thick sputum, which may at times even be tinged with blood. Therefore, cough character, although helpful, should not limit the differential diagnosis. A variety of qualities attributed to cough character have been described that can be useful starting points in the evaluation of cough, including paroxysmal for pertussis; staccato for *Chlamydia* infection; barking for laryngotracheal infection; throat

clearing for postnasal secretions; and honking for habit cough syndrome. History and pattern of illness progression are crucial for putting these cough qualities into perspective. For example, cough that occurs only during the daytime, increases with attention, and does not limit or change with physical activity is more likely habit cough syndrome. However, such a cough can also indicate tracheal pathology if it does not possess all of these characteristics. In contrast, if the cough clearly increases with activity and limits the child from participating in desired physical activities, then asthma is a likely diagnosis. Night cough is frequently seen with asthma; however, when nasal symptoms are present it could also suggest allergy or sinusitis (or both) as triggers; cough during feeding suggests swallowing dysfunction or tracheoesophageal fistula with aspiration; and cough after feeding with spitting up, retching, or arching of the back suggests gastroesophageal (GE) reflux.

Age of onset is also an important feature in planning a workup. Chronic or recurrent cough that begins in early infancy, especially in children younger than 3 months, suggests a congenital or anatomic origin and clearly requires a more aggressive evaluation. These children are also at risk for protracted bacterial bronchitis, although the effect of this entity is still being delineated. Similarly, an aggressive approach should be considered when cough begins relatively suddenly, especially in toddlers, since this might suggest foreign-body aspiration. In both of these scenarios visualization of the airway using bronchoscopy should be considered early in the evaluation process. Cough beginning at more than 6 months of age may suggest airways hyperreactivity, and a therapeutic trial of treatment with a  $\beta$ -2 agonist may be a reasonable first step. Cough beginning relatively suddenly in adolescents, especially at times of psychosocial stress, might indicate a psychogenic origin.

Classifying cough in this way, using key historical information, can provide a useful starting point in developing a differential diagnosis. Studies have shown that an organized approach to the assessment and management of cough can greatly improve diagnostic and treatment success.

## EVALUATION

### History

#### Personal and Family History

The history from a patient complaining of cough should begin with an accurate description of the cough, with a focus on the pattern and progression of symptoms. The duration of cough; the frequency of discrete cough episodes; quiet periods between cough (daily cough vs days or weeks between cough episodes); and the quality, timing, and triggers of the cough are all important pieces of information to help make an accurate diagnosis. Associated fever suggests a respiratory tract infection; cough worsening with exercise suggests asthma; and night cough in the absence of any other daytime symptomatology may suggest a postnasal drip, as with allergy or sinusitis. Past history is also important. Previous episodes, especially with a recurrent pattern of spring and fall

seasonal variation, may suggest allergy, and chronic cough with poor weight gain suggests a more severe systemic illness such as cystic fibrosis or an immune deficiency. Family history can be especially helpful with more chronic symptoms. A family history of allergies, atopy or asthma makes these diagnoses far more likely in the child with chronic or recurrent cough, given that a history of asthma or atopy in first-degree relatives confers a 2- to 4-fold increase in risk of asthma in the child. Similarly, a family history of early childhood death related to infection makes an immune deficiency more likely.

### Neonatal History

Neonatal history is similarly important because pre-term infants are more likely than full-term infants to have persistent airways hyperreactivity, laryngotracheomalacia, and GE reflux. Infants with poor Apgar scores, perinatal hypoxia, or a difficult postnatal course may have central nervous system sequelae and therefore have suck or swallow dysfunction, increasing the risk of aspiration. Finally, associated congenital abnormalities (eg, diaphragmatic hernia) may result in pulmonary hypoplasia, leading to chronic respiratory dysfunction and recurrent pneumonia.

### Environmental History

Environmental history is also important in determining the source of cough. Children who live in households with smokers have significantly more respiratory infections and asthma symptoms than children not exposed to secondhand smoke. Exposure to molds from household water leaks, decaying garbage, vegetation or ineffective cleaning of bathroom tile; dust mites from mattresses, pillows, stuffed animals, or forced air heating systems; and roaches, mice, and household pets all increase the risk of allergy and asthma symptoms. Exposure to other children through school, child care, babysitters, or school-aged siblings all make recurrent respiratory tract infections far more common. Even thirdhand smoke, residual chemicals from tobacco use which remain on surfaces such as walls, clothing, and even hair, may play a role in chronic cough.

### Physical Examination

The physical examination plays a critical role in pinpointing the trigger for the cough and identifying signs of a more serious underlying or chronic condition. A nasal speculum examination can help determine the color and quality of the nasal mucosa, as well as the presence or absence of nasal secretions. Inflamed nasal mucosa, coupled with thick secretions, suggests rhinitis; when the symptoms have been prolonged, sinusitis can be considered. Associated maxillary, ethmoid or frontal sinus tenderness and pharyngeal drip with a cobblestone appearance (lymphoid hyperplasia) further support the diagnosis of sinusitis. Halitosis may also be present. In contrast, pale, boggy, swollen nasal mucosa makes allergic rhinitis more likely. Associated atopic symptoms, such as eczema, further support this diagnosis. Other features of the pharyngeal examination can also be helpful. Chronic pharyngeal inflammation, in the absence of

other signs of acute infection, suggests GE reflux. Oral mucosal ulcerations or thrush suggests an immune deficiency. When pertussis is a consideration, cough paroxysms triggered by a tongue depressor support the diagnosis. Signs of an acute infectious process, such as fever, adenopathy, pharyngitis, or rash, are important to appreciate but do not necessarily rule out a predisposing condition, especially when the pattern of illness suggests chronicity or frequent recurrence. A thorough assessment of other body systems is important in judging whether a more global workup is necessary. Growth failure, poor developmental milestone achievement, clubbing, heart murmurs, hepatosplenomegaly, and chronic lymphadenopathy are all potential clues to a more severe underlying process.

A thorough examination of the respiratory system is critical in making an accurate diagnosis. Stridor and inspiratory rhonchi or wheeze suggest upper and large central airway disease, whereas rales, expiratory rhonchi, and wheeze are indicative of lower or distal airway inflammation. Similarly, a change in the quality of air exchange can be an early finding in asthma and other diseases of airways obstruction.

An accurate lower airway examination depends on the cooperation of the patient. Wheeze and distal airway sounds can be masked by a patient's vocalization or crying. Similarly, force of airflow insufficient to uncover milder changes may mask both inspiratory and expiratory findings in infants and children who do not take deep breaths on command. Every effort should be made to place the child at ease during the examination. Game playing, such as blowing on a feather or blowing up a balloon, can be helpful. In younger children and infants, the examiner can mimic a forced expiratory maneuver by firmly but gently compressing the anteroposterior chest wall inward once the child has begun voluntary exhalation. This approach will frequently uncover milder degrees of wheezing previously not appreciated with passive breathing. The examiner should allow the child to begin exhalation passively before performing this maneuver to ensure that the glottis is relaxed and the procedure proceeds safely and effectively.

### Laboratory Evaluation

#### Hematologic Tests

Acute cough rarely needs extensive laboratory assessment. A detailed history and physical examination are usually sufficient to reach an accurate presumptive diagnosis, and response to empiric therapy will confirm this assessment. In cases where this approach does not lead to a resolution of symptoms, or when the cough is either recurrent or chronic, an organized approach using a standardized algorithm has proven to be very helpful in identifying the cause and optimizing treatment, thereby shortening the duration of cough. A complete blood cell count (CBC) with differential may help distinguish a bacterial from a viral cause if infection is suspected. However, localized infections such as sinusitis are not always accompanied by an elevated white blood cell count with a shift to the left. The total eosinophil count on the CBC may be an important clue to atopy. Similarly, an elevated IgE level or positive nasal smear for eosinophils would

further corroborate the diagnosis of allergy and suggest the possibility of asthma. Although increased polymorphonuclear leukocytes on a nasal smear may suggest rhinosinusitis, the result is difficult to quantify, and the test may be misleading. Ultimately, if sinusitis is suspected, empiric therapy should be initiated based on history and physical examination, and response to therapy should be monitored. Advanced imaging techniques (computed tomography) can be considered in complicated cases.

### **Gastroesophageal Tests**

When aspiration or GE reflux (although the effect of GE reflux as a trigger for cough has not been clearly proven) is a consideration, a barium swallow (modified for aspiration and standard for GE reflux) may be useful. Although barium swallow is of limited use in diagnosing GE reflux (approximately 40% false negative), looking for anatomic causes related to esophageal abnormalities such as partial obstruction, tracheoesophageal fistulae, and vascular rings, is important in infants. Monitoring with a pH probe is the gold standard for diagnosing GE reflux; however, many experts suggest a period of empiric therapy if reflux is suggested by history and physical examination findings, with the pH probe being reserved for patients in whom primary empiric treatment fails.

### **Pulmonary Function Tests**

Early use of pulmonary function testing can be very helpful in making the distinction between upper and lower airways disease and differentiating obstructive from restrictive changes. Children must be old enough to exhale fully and inhale forcefully on command, and the test should be reproducible to ensure accuracy and reliability of results.

Flattening of the inspiratory portion of the flow-volume loop suggest upper airway obstruction, whereas changes in the ratio of the forced expiratory volume in the first 1 second to the forced vital capacity of the lungs ( $FEV_1/FVC$ ) or the forced midexpiratory flow rate over the middle half of the FVC ( $FEF_{25\%-75\%}$ ) indicate airways obstruction consistent with distal disease. Reversibility of these changes (20% improvement) with a  $\beta$ -2 agonist confirms the diagnosis of asthma and leads to effective therapy.

In younger children, 3 to 6 years old, impulse oscillometry may be used to assess airways resistance and response to bronchodilators. This can be helpful in children too young to perform formal spirometry. Infant pulmonary function testing can be used in even younger ages; however, the results are less reliable and require a high level of expertise to be performed accurately.

### **Other Tests**

Chest radiograph is important when cough is chronic and no clear diagnosis is evident on first assessment. Other tests, such as the sweat test, tuberculin skin test, immunologic studies, and alpha-1 antitrypsin levels (although these patients characteristically present with lung disease in the third or fourth decade of life), can all be useful in the proper clinical setting. Bronchoscopy can be useful to diagnose

abnormalities of both the upper and lower airways and should be considered in patients with chronic symptoms not responsive to empiric treatment. It is especially helpful in confirming the diagnosis of protracted purulent bronchitis and directing appropriate antimicrobial therapy. Furthermore, it is the test of choice when a foreign body or chronic aspiration are considered likely. In cases in which an upper airways origin is likely, flexible bronchoscopy (vs laryngoscopy) is still preferred to make the definitive diagnosis since lesions below the vocal cords up to the thoracic inlet can still be the cause of upper airway symptomatology.

## **TREATMENT**

Once the history and physical examination have led to an initial assessment, the fact that cough is a symptom of an underlying condition should be discussed with the patient and family. Treatment of the underlying disorder (if necessary) should always be the prime focus. Empiric therapy, based on primary assessment, can be a reasonable starting point. Judicious use of laboratory testing, as previously discussed, can be helpful in confirming the diagnosis and allaying parental anxiety. Furthermore, in some conditions, cough is an important component of the body's natural response to the primary illness, and suppressing the cough in the absence of effective therapy of the primary disorder may actually worsen the problem.

Treatment of the underlying disorders causing cough is discussed in other sections of this book; this chapter is limited to a review of medications used to treat cough itself. The decision to use a cough medicine as an adjunct to the treatment of the primary disease is left to the primary care physician and family. When cough is limiting or otherwise debilitating the patient, symptomatic treatment may be attempted; however numerous studies question whether over-the-counter cough preparations offer any significant clinical benefit. In addition these cough and cold medications should not be given to children younger than 4 years because serious and potentially life-threatening side effects can occur from their use. Finally, several studies have shown that honey may be beneficial in children older than 2 years of age.

### **Expectorants**

Expectorants such as guaifenesin (formerly known as glyceryl guaiacolate) may be used in an attempt to make secretions more fluid and reduce sputum thickness, however the effectiveness of this treatment has been called into question. This therapeutic approach may be useful when drainage of secretions is important, as with sinusitis. Because expectorants work by increasing the fluid content of secretions, water is probably the most effective expectorant. Saline nose sprays can make secretions more fluid and easily cleared by the patient and systemic hydration, but not overhydration, should always be optimized. Despite widespread use, expectorants have not been shown to decrease cough in children. Other older expectorants, such as potassium iodide and ammonium chloride, are no longer prescribed to children because of their adverse effects when used at effective doses.

### Mucolytic Agents

Acetylcysteine was previously used as a mucolytic agent to help liquefy thick secretions, especially in diseases such as cystic fibrosis; however, its propensity for inducing airway reactivity and inflammation has lately made it less popular.

### Cough Suppressants

Cough suppressants, which can be divided into peripheral and centrally acting agents, can be effective in transiently decreasing cough severity and frequency. Peripheral agents include demulcents (eg, throat lozenges), which soothe the throat, and topical anesthetics, which can be sprayed or swallowed. Topical agents block the cough receptors, but their effects are short-lived because oral secretions rapidly wash them away. Centrally acting cough suppressants, including both narcotic and nonnarcotic medications, suppress the cough reflex at the brain stem level. The narcotic agent most commonly used in children is codeine. Although it has been shown to be effective in adults, studies on its safety and efficacy in children are lacking. Furthermore, data from adults should not be extrapolated to children, particularly those younger than 2 years, because the metabolic pathway for clearance of codeine is immature in infants. In older children, codeine should still be avoided and only used in extreme cases and with very clear instructions because of the unpredictable and potentially dangerous variation of its metabolism in the pediatric population. Other agents, such as hydrocodone, have no demonstrated advantage and pose a greater risk of dependency. Dextromethorphan (the dextro-isomer of codeine) is the most commonly used nonnarcotic antitussive; and despite data from adults, evidence of efficacy for children is lacking.

### Decongestants

Decongestants such as pseudoephedrine can be used either topically or systemically to decrease nasal mucosal swelling. Decongestants can also facilitate sinus drainage by decreasing sinus ostia obstruction, and may work well in combination with expectorants to optimize treatment of chronic sinusitis. Care should be taken in the use of these agents because they have been shown to lead to tachyarrhythmias in individuals who use them in excess. In addition, these agents have not been studied in children and should be avoided in children younger than 2 years. Multiple reviews of the data from children between 2 and 6 years old also show lack of efficacy combined with a risk of side effects in this age group. It is therefore recommended that these agents not be used in children younger than 6 years.

### Antihistamines

Antihistamines, which can be helpful in the treatment of cough triggered by allergy, have minimal effect when cough is the result of viral or bacterial infection and may actually be detrimental because they can increase the thickness of secretions. First-generation H<sub>1</sub>-receptor antagonists may decrease nasal drip by exerting an anticholinergic effect. Additionally,

diphenhydramine may have a modest direct effect on the medullary cough center. The clinical benefits of these agents are unclear.

### WHEN TO REFER

- Cough persists despite adequate therapy of primary disease
- Cough thought to be from hyperreactive airways is not easily reversible with  $\beta$ -2 agonist
- Cough recurs more frequently than every 6 to 8 weeks
- Cough associated with failure to thrive
- Cough associated with other systemic illness

### WHEN TO ADMIT

- Patient has respiratory distress
- Infant is unable to feed
- Cough is associated with bacterial pneumonia not responsive to oral antibiotic trial

## Chapter 136 CYANOSIS

H. Michael Ushay, MD, PhD

### INTRODUCTION

Cyanosis is a bluish purple appearance of the skin or mucous membranes usually caused by an increased concentration of deoxygenated (unsaturated or reduced) hemoglobin (Hgb). While occasionally a benign finding, as in a healthy newborn with acrocyanosis or when observed in the lips and fingers of a child who has been in the cold ocean, acute cyanosis often indicates a significant reduction in oxygen concentration and may signify a life-threatening event. The presence or history of cyanosis requires careful evaluation.

Cyanosis occurs in all ages and may be the result of congenital or acquired disorders of the respiratory or cardiovascular systems. In the neonatal period, persistent pulmonary hypertension of the newborn (PPHN) and congenital heart disease are common causes of cyanosis, while respiratory disorders are the most common cause of life-threatening cyanosis in older children.

Observed most easily in the nail beds, the lips, mucous membranes of the mouth, the ears, the conjunctivae, and the tip of the nose, cyanosis is especially visible in buccal mucosa and beneath the tongue. At these locations, capillary beds are close to the surface and arterial and venous blood are seen together. Cyanosis can be present peripherally, centrally on the head and trunk, and also differentially with only lower parts of the body affected. The location where cyanosis is observed can help in determining the cause.

Cyanosis is made worse by vasoconstriction, so a patient should be examined in a warm environment. The perception of cyanosis depends on the quality of ambient lighting and by an examiner's ability to perceive subtle shades of blue.

To most observers, cyanosis becomes visible when the concentration of deoxygenated Hgb approaches 3 to 5 g/dL, but some reports suggest that the threshold for detecting cyanosis may be as low as 1.5 g/dL. The appearance of cyanosis is related to the absolute concentration of deoxygenated Hgb rather than to a specific oxyhemoglobin saturation (SaO<sub>2</sub>). Cyanosis in a patient with a Hgb concentration of 15 g/dL will be apparent at an arterial SaO<sub>2</sub> somewhere between 70% and 80%: 5 g/dL of Hgb is desaturated at 70% arterial saturation, and 3 g/dL is desaturated at 80% saturation. The higher the patient's Hgb concentration, the

more readily cyanosis becomes evident. For example, 5 g/dL represents one-half of the Hgb in a child with 10 g/dL but only one-third in a patient with 15 g/dL of Hgb. Thus, as Hgb concentration falls, cyanosis becomes apparent only at lower oxyhemoglobin saturations. Because Hgb concentration varies in both healthy and ill children and throughout life, cyanosis appears at different degrees of desaturation in different children and at different times.

Whereas patients becoming progressively more anemic do not manifest cyanosis until their oxygen saturations have fallen substantially, a patient who is polycythemic with a Hgb concentration of 20 g/dL, for example, might manifest cyanosis when 92% saturated (1.5 g/dL desaturated Hgb) and certainly when 75% saturated (5 g/dL desaturated Hgb). It is important to remember that in an anemic patient, a severe degree of oxygen desaturation can occur without cyanosis. Although cyanosis is always a concern, the absence of cyanosis is not necessarily reassuring in a patient with respiratory distress.

The arterial Hgb oxygen saturation measured with a pulse oximeter is referred to as SpO<sub>2</sub> to distinguish it from a saturation measurement obtained from an arterial blood gas (ABG), which is referred to as SaO<sub>2</sub>. SpO<sub>2</sub> and SaO<sub>2</sub> are often used interchangeably and are usually almost identical in the absence of significant amounts of carbon monoxide, methemoglobinemia, elevated bilirubin levels, or very poor perfusion. A pulse oximeter measures SaO<sub>2</sub> directly and permits the recognition of decreasing degrees of SaO<sub>2</sub> before cyanosis becomes visible. Screening newborns using pulse oximetry detects degrees of Hgb desaturation indicative of congenital heart disease that may not be obvious on examination.

In an ABG sampling, the pH, PCO<sub>2</sub>, PO<sub>2</sub>, and SaO<sub>2</sub> are determined in addition to other values. Depending on the type of ABG analyzer, the SaO<sub>2</sub> is measured directly in a process called co-oximetry or is calculated based on the pH, PCO<sub>2</sub>, PO<sub>2</sub>, and oxyhemoglobin dissociation curve.

### CENTRAL AND PERIPHERAL CYANOSIS

Cyanosis is described as being *central* or *peripheral* in origin. Central cyanosis occurs when the origin of desaturation is either an oxygenation defect of the lungs or the result of addition of venous blood to arterial blood from shunts or mixing lesions in the heart. In central cyanosis, the arterial blood leaving the heart is desaturated. Peripheral cyanosis occurs when blood leaves the heart and lungs fully saturated, but, from either excessive tissue oxygen extraction or sluggish blood flow in tissue beds (including some, such as the nail beds or lips, that are visible), the venous blood becomes desaturated to the extent that cyanosis becomes evident. Whether cyanosis is central or peripheral is a function of the physiologic dysfunction rather than where the cyanosis is evident on physical examination.

*Acrocyanosis* refers to bluish color in the hands and feet and around the mouth (circumoral cyanosis). The mucous membranes generally remain pink. A form of peripheral cyanosis that usually reflects benign vasomotor changes in the affected extremities, acrocyanosis

does not indicate pathology unless cardiac output is extremely low, resulting in severe venous desaturation from increased oxygen extraction.

In the newborn, acrocyanosis is a striking example of cyanosis arising from intense peripheral vasoconstriction and variable perfusion in the extremities compared with the central circulation. It is seen in well babies and resolves within the first few days of life.

Acrocyanosis may also occur in infants when they cry, regurgitate, vomit, cough, or hold their breath. This finding is often very alarming to the caregiver who witnesses the event, and it requires careful questioning and observation to differentiate it from serious underlying pathology (eg, seizure, apneic episode, cardiac arrhythmia, congenital heart defect). The child with acrocyanosis typically does not have major changes in mental status during the event and appears well on physical examination.

Moderate cold exposure slows the transit time of blood through capillary beds and allows for increased unloading of oxygen from the blood to the tissues in infants and young children, leading to cyanosis, especially in the lips and perioral region. This form of acrocyanosis rapidly resolves with warming of the patient.

## OXYGEN CONTENT, DELIVERY, AND TRANSPORT

Because deoxygenated Hgb has a dark blue to purplish color, the higher the concentration of desaturated Hgb, the bluer the blood and the more cyanotic the patient appears. Hgb desaturation and hence cyanosis result from disorders of oxygen uptake, transport, and utilization.

In an intact postnatal circulation, venous blood with a saturation of approximately 75% travels via the pulmonary artery to the pulmonary capillary bed where it becomes fully saturated upon exposure to oxygen from the alveolus across the alveolar capillary membrane. Fully oxygenated blood returns to the left atrium via the pulmonary veins and from there moves through the left ventricle to the aorta.

Oxygen in the blood is either bound to Hgb or dissolved in plasma. The amount bound to Hgb is reflected by the oxyhemoglobin saturation, and the amount dissolved in plasma is measured by the  $\text{PaO}_2$ . The role of oxyhemoglobin saturation on the oxygen content of blood is described by the equation

$$\text{CaO}_2 = [\text{Hgb}] \times \text{SaO}_2 \times 1.36 \text{ mL/g} + 0.003 \times \text{PaO}_2$$

where  $\text{CaO}_2$  is the oxygen content,  $[\text{Hgb}]$  is the concentration of hemoglobin in g/dL,  $\text{SaO}_2$  is the oxyhemoglobin saturation, 1.36 mL/g is the binding capacity for oxygen in mL/g of Hgb, and  $\text{PaO}_2$  is the tension of dissolved (unbound) oxygen in the plasma. Approximately 97% of the oxygen in blood is bound to Hgb, leaving only a small amount unbound and dissolved in blood. Delivery of oxygen to the tissues is a function of the flow of blood produced by the systemic ventricle of the heart (cardiac output) and the oxygen content of the blood.

In a normal circulation, beyond the neonatal period, arterial blood with an oxyhemoglobin saturation of

95% to 98% flows to capillary beds throughout the body, where in the course of traversing the tissue beds approximately 25% of the Hgb-bound oxygen molecules are offloaded to the tissues. This is known as oxygen consumption or utilization. The end-capillary oxyhemoglobin saturation is, on average, about 25% less than at entrance to a capillary bed. Some tissues will extract more oxygen and some may extract less. The 25% difference in oxygen content between arterial and venous blood is relatively conserved as long as cardiac output is adequate to meet tissue oxygen demands. In tissue beds with reduced cardiac output (blood flow), a higher proportion of oxygen is drawn from Hgb, resulting in greater than 25% extraction.

Hypoxemia is the term used to describe decreased oxygen tension ( $\text{PaO}_2$ ) and saturation ( $\text{SaO}_2$ ) of arterial blood. Hypoxia is the state that occurs when inadequate oxygen is delivered to tissues with resultant decreased function and a transition to anaerobic respiration.

With oxygenated arterial blood appearing red and deoxygenated venous blood usually appearing dark red or bluish, the color of a capillary bed becomes a function of the relative amounts of arterial and venous blood present in the bed. The more deoxygenated Hgb present, the bluer (cyanosed) the capillary bed appears to be. When cardiac output to a tissue falls below normal, more than 25% of oxygen may be extracted from each Hgb molecule to meet the metabolic requirements of the tissue. This increased off-loading will result in a decrease in oxyhemoglobin saturation for the end capillary blood and an increase in the arterial to venous oxygen content difference, thus making cyanosis more prominent. As the oxyhemoglobin saturation of the end capillary blood decreases, cyanosis becomes obvious.

In circumstances in which the Hgb of the arterial blood entering a capillary bed is not fully saturated with oxygen, venous blood leaving the capillary bed will be desaturated to an even greater degree and the capillary beds will look even more cyanotic. For example, if arterial blood enters a capillary bed with an oxyhemoglobin saturation of 85%, the resultant venous blood may have an oxyhemoglobin saturation of 60% after the off-loading of 25% of oxygen molecules. Thus, the blood in the capillary bed will look cyanotic. The preservation of an arterial to venous oxygen content difference of approximately 25% is used as a surrogate indicator of adequate cardiac output and tissue oxygen delivery. In the presence of adequate cardiac output and an appropriate Hgb concentration, adequate tissue oxygen delivery can occur even in the presence of significantly desaturated or cyanotic arterial blood.

## PULMONARY MECHANISMS OF CYANOSIS

The Hgb desaturation of central cyanosis can result from pathology of the airways, lungs, heart, or Hgb itself. Normally, Hgb is close to 100% saturated with oxygen when it leaves the alveolar capillary unit and slightly less than 100% when it leaves the left ventricle—there is a normal, very small amount of

venous blood shunted to the blood entering the left side of the heart from the lungs. With pulmonary disease, a disturbance of alveolar gas exchange may result in desaturated blood entering the pulmonary veins and left atrium. The desaturation of pulmonary venous blood is a key factor distinguishing desaturation caused by pulmonary disease from desaturation caused by congenital heart disease. In congenital heart disease, pulmonary venous blood is usually fully saturated even when systemic saturations may be very low. Five pathophysiologic mechanisms explain why blood does not become fully oxygenated as it travels through the pulmonary alveolar capillary beds. These 5 mechanisms of hypoxemia are mismatching of alveolar ventilation to perfusion, intrapulmonary shunt, hypoventilation, diffusion block, and breathing hypoxic gas mixtures.

In patients with parenchymal lung disease such as pneumonia, ventilation-perfusion (V/Q) mismatch is the most important mechanism for hypoxemia. For blood to become fully oxygenated, the flow of blood to an alveolar-capillary unit must match the ventilation in the unit. V/Q mismatching occurs when the relationship of alveolar ventilation to capillary bed perfusion is not appropriately balanced. The matching of ventilation to perfusion is along a continuum. At 1 extreme are alveolar capillary units that are ventilated but not perfused; these are described as having dead space ventilation ( $V/Q = \infty$ ). At the other extreme are lung units that are perfused but not ventilated ( $V/Q = 0$ ); these are described as intrapulmonary shunt, occurring when blood travels through the lungs from the right side of the heart to the left without being exposed to aerated alveoli. Between the 2 extremes is a continuous range of V/Q ratios that, overall, result in a normal ABG. In lung diseases such as acute respiratory distress syndrome, pneumonia, bronchiolitis, pulmonary edema, and asthma, most hypoxemia is the result of V/Q mismatching with only a small component from intrapulmonary shunt.

Hypoventilation occurs in patients with neurologic, traumatic, pharmacologic, or chemical suppression of respiratory drive, as well as with suffocation. A patient who develops apnea or acute upper airway obstruction caused by a foreign body will become profoundly hypoxemic and very rapidly become cyanotic. Cyanosis associated with viral laryngotracheobronchitis (croup) or pertussis (whooping cough) are examples of hypoventilation-induced hypoxemia. Any acquired or congenital abnormality of the airway that obstructs airflow can potentially cause significant hypoventilation and result in hypoxemia to the extent that cyanosis becomes apparent.

Breathing hypoxic gas mixtures occurs when victims are trapped in a hypoxic environment such as a closed-space fire or when exposed to high concentrations of gases such as methane and helium that are not in themselves toxic but induce hypoxia by displacing breathable oxygen. Another example of breathing hypoxic gas is the effect of altitude on barometric pressure. At higher altitudes, the barometric pressure, and hence the amount of oxygen available to breathe, is lower: arterial  $PaO_2$  and  $SaO_2$  thus fall in proportion to the decrease in barometric pressure.

Diffusion block occurs when the interstitial space between the pulmonary capillary and the alveolus becomes so thickened or damaged that oxygen cannot move from the alveolus to the capillary. Diffusion block is seen with pulmonary fibrosis.

The  $SaO_2$  of arterial blood depends on the effectiveness of oxygen transfer at the alveolar level but is also affected by the shunting of venous blood into the systemic arterial system through the heart or lungs. The addition of desaturated venous blood to oxygenated blood is called *venous admixture* and is the mechanism behind intrapulmonary shunt. The resultant saturation of the arterial blood is proportional to the amount and saturation of the combined blood volumes. It is the  $SaO_2$  and oxygen content of the blood volumes that are being combined that influence the resultant saturation, not the  $PaO_2$ . Breathing 100% oxygen for a prolonged time can partially correct desaturation resulting from alveolar hypoventilation, diffusion block, or V/Q mismatching, but does not correct hypoxemia resulting from intrapulmonary shunt.

## PULMONARY VERSUS CARDIAC CYANOSIS

Distinguishing whether a sick newborn or child is cyanotic for pulmonary or cardiac reasons is challenging. Cyanotic heart disease may mimic respiratory disease and vice versa. Tachypnea, retractions, nasal flaring, and grunting point toward a pulmonary cause of cyanosis. Patients with anatomic cardiac lesions as the cause of cyanosis are generally somewhat distressed from a respiratory standpoint but to a somewhat lesser extent than found with purely respiratory disease. In cyanosis from PPHN, there may be a history of a difficult delivery, meconium-stained amniotic fluid, meconium aspiration, perinatal sepsis, asphyxia, and low Apgar scores. Because there is often a component of meconium aspiration pneumonia, these newborns demonstrate severe respiratory distress.

Pulse oximetry should be obtained immediately with any suggestion of cyanosis. A hyperoxia test (see following text) may help distinguish hypoxemia for respiratory reasons, such as pneumonia or neonatal respiratory distress syndrome, from hypoxemia caused by congenital heart disease or PPHN. Early in life, the  $PaO_2$  may increase to greater than 100 mm Hg in infants with forms of cyanotic heart disease with high pulmonary blood flow such as total anomalous pulmonary venous return (TAPVR). If there is an inadequate rise in  $PaO_2$  or oxygen saturation from a hyperoxia test, echocardiography should be performed immediately to ascertain the presence or absence of a congenital heart lesion. In general, echocardiography should be performed to assess for the possible presence of congenital cyanotic heart disease (CCHD) whenever hypoxemia is not responsive to supplemental oxygen or mechanical ventilatory support.

## CYANOSIS WITH PULMONARY DISEASE

Lower airway diseases, such as viral bronchiolitis, pneumonia, and status asthmaticus, can cause cyanosis from V/Q mismatching and small degrees of intrapulmonary shunt. Bronchiolitis, most often caused by

respiratory syncytial virus (RSV), is a common disease process affecting infants in winter months. The airways become edematous and infiltrated with inflammatory cells, ultimately obstructing the lumens. In addition to signs and symptoms of respiratory distress such as tachypnea, retractions, grunting, and nasal flaring, RSV bronchiolitis is also associated with apnea that can induce deep cyanosis by hypoventilation.

Pertussis caused by *Bordetella pertussis* or *parapertussis* is often associated with cyanosis. In the paroxysmal phase, coughing paroxysms without an intervening breath can result in deep visible cyanosis. As the illness progresses over time, patients can turn blue after only a few coughs.

Upper airway obstruction presents with inspiratory symptoms often manifested as stridor, a harsh, sometimes high-pitched sound produced by vibration of upper airway structures upon inspiration. An infant with significant upper airway obstruction and stridor often demonstrates substernal retractions. Worrisome symptoms are change in voice, muffling or hoarseness, and difficulty in swallowing and handling secretions.

Croup, usually from infection with the parainfluenza virus, is the most common cause of stridor in children. Less common inciting agents include influenza, adenovirus, measles, and RSV. Croup usually occurs in children aged 6 months to 3 years. The pathophysiology involves endothelial damage, mucous production, loss of ciliary function, and edema of the subglottic region. Infants present with a history of a preceding upper respiratory infection, low-grade fever, characteristic barking cough, and inspiratory stridor. Airway radiographs may reveal subglottic narrowing.

Epiglottitis is a life-threatening bacterial infection of the epiglottis and supraglottic structures, usually caused by *Haemophilus influenzae*. Patients present with high fever, toxic appearance, and stridor. The incidence of epiglottitis has decreased significantly since the introduction of the *Haemophilus influenzae* vaccine.

Aspiration of foreign bodies is relatively common and can cause severe respiratory distress and cyanosis when an object is lodged in the trachea. Foreign body aspiration should be suspected in an afebrile infant with acute onset of coughing, choking, stridor, or wheezing. Many foreign bodies are not radiopaque, and physicians should thus have a high index of suspicion regardless of radiographic findings.

Laryngomalacia, choanal atresia or stenosis, subglottic stenosis, tracheomalacia, bacterial tracheitis, and obstructive sleep apnea are other causes of airway obstruction that may present with cyanosis.

## CYANOSIS WITH HEART DISEASE

Pediatric heart disease of several different types can result in cyanosis. CCHD results in cyanosis either from mixing of venous blood with arterial blood through intra- and extracardiac shunts or from insufficient pulmonary blood flow.

Heart disease that causes pulmonary venous congestion can result in cyanosis by leading to pulmonary edema, which forms when increased left atrial pressure

is transmitted back to the pulmonary veins and further back to the pulmonary capillary bed. Increased pressure on the venous side of the pulmonary capillary bed results in transudation of fluid from the capillary to the interstitium and from there to the alveoli. The presence of edema fluid in the alveoli overwhelms the pulmonary lymphatics, deactivates pulmonary surfactant, and results in alveolar flooding and collapse. The resulting ventilation perfusion mismatching and intrapulmonary shunt can cause severe hypoxemia and even cyanosis. Diseases that can cause cyanosis by this mechanism include mitral stenosis and mitral regurgitation. With severe systolic and diastolic dysfunction of the left ventricle, such as may result from acute myocarditis, elevated left atrial pressure can lead to the formation of pulmonary edema as described above. In dilated cardiomyopathy, the left heart can dilate to the point that the mitral valve no longer effectively separates the left atrium from the left ventricle and, with each systole, there is retrograde flow of blood into the left atrium and pulmonary veins, leading to pulmonary edema. A similar effect occurs when the mitral valve leaflets are damaged by rheumatic heart disease.

A typically noncyanotic heart lesion such as a ventricular septal defect (VSD) can result in cyanosis with the development of Eisenmenger syndrome. With a VSD, blood flows from the left ventricle to the right ventricle because of the lower resistance of the pulmonary vascular system. There is no cyanosis. However, if the VSD is unrestrictive to flow and the lesion is not corrected over time, the extra volume of blood eventually induces hypertrophic changes in smooth muscles of the pulmonary arteries with a resultant increase in pulmonary vascular resistance. The pulmonary vascular resistance may become so high that the shunt reverses direction, with blood moving in a right-to-left direction through the VSD. This results in venous blood mixing with arterial blood in the left ventricle and the development of severe desaturation and cyanosis. Fortunately, with early repair of VSDs, Eisenmenger syndrome is seen very rarely. It may be seen, however, in parts of the world where access to repair of congenital heart lesions is not readily available.

## Congenital Cyanotic Heart Disease

Cyanosis in VSD and heart failure as described above is rare; but cyanotic heart disease always results in significant cyanosis. An infant with CCHD typically develops cyanosis in the first few hours of life. Initially, cyanosis may be noticeable with crying or feeding and generally without evidence of respiratory distress. In these lesions, a patent ductus arteriosus (PDA) serves either as a means to deliver blood from the aorta to the pulmonary artery so it can be oxygenated in the lungs (left-to-right shunt) or as a means of maintaining systemic blood flow (right-to-left shunt). In many cases, patients with cyanotic heart disease either deteriorate hemodynamically or become progressively more cyanotic as the PDA closes.

The lesions of CCHD can be placed into different groups. One group, consisting of tetralogy of Fallot (TOF), pulmonary atresia, tricuspid atresia, pulmonic stenosis, and Ebstein anomaly, creates cyanosis by

obstructing pulmonary blood flow with resultant shunting of blood from the right to left side of the circulation. In dextro-transposition of the great arteries (d-TGA) and TAPVR, on the other hand, pulmonary blood flow may be normal or increased, but pulmonary venous return is anatomically separated from the systemic arterial circulation. In truncus arteriosus and double outlet right ventricle (DORV), there is mixing of arterial and venous blood with consequent cyanosis. Another group of lesions includes the left-sided obstructive lesions of hypoplastic left heart syndrome (HLHS), critical coarctation of the aorta and interrupted aortic arch that produce desaturation because of dependence on right-to-left shunting through a PDA to maintain systemic perfusion.

Simultaneous upper and lower extremity pulse oximetry measurements can be diagnostic. An  $\text{SaO}_2$  that is higher in the right arm than in the umbilical artery or lower extremities indicates that venous blood has been added to the aorta at the level of the ductus arteriosus and is known as *differential cyanosis*. With d-TGA in the presence of pulmonary hypertension or coarctation of the aorta, the saturation in the right arm is less than in the lower extremities because oxygenated blood is added to desaturated blood at the level of the PDA; this is called *reverse differential cyanosis*.

If the patient is not at a facility where echocardiography can be performed, immediate transport should be arranged to such a center. Stabilization should include initiation of an infusion of prostaglandin E1 (PGE1) at a dose of 0.05 mcg/kg/min if there is any suspicion of ductal dependent heart disease. PGE1 dilates the ductus arteriosus to provide adequate pulmonary or systemic blood flow. In that the benefits of prostaglandin are lifesaving and the drawbacks minimal, the threshold should be very low for initiating PGE1 therapy until ductal dependent heart disease is ruled out. The PGE1 infusion can be increased to a dose of 0.15 mcg/kg/min if no improvement in saturation and pulses is seen soon after initiation. It is appropriate to administer PGE1 to any infant in whom the diagnosis of CCHD is strongly suspected, even before a complete evaluation is performed. Potential side effects of PGE1 include apnea, jitteriness, seizures, and peripheral vasodilation with hypotension, as well as an increased risk of infection. Fluid administration may be necessary if vasodilation leads to hypotension, and respiratory support including intubation may be required if significant apnea occurs.

### Abnormalities of the Right Ventricular Outflow Tract

Tetralogy of Fallot, the most common congenital heart lesion that can cause cyanosis, consists of VSD, pulmonic stenosis, right ventricular hypertrophy, and an overriding aorta. On examination, the systolic murmur of pulmonic stenosis might be appreciated. Chest radiographs reveal normal cardiac size, with a rounded, uplifted apex and concavity at the site of the pulmonary artery, a “boot-shaped” heart. There is diminished pulmonary vasculature. Electrocardiogram demonstrates right axis deviation and right ventricular hypertrophy.

With TOF, the degree of cyanosis depends on the severity of the right ventricular outflow tract obstruction. With more severe pulmonic stenosis, right ventricular pressure increases and blood is shunted across the septal defect from the right to the left ventricle, bypassing the lungs. In infants with mild obstruction, symptoms of heart failure from the large VSD are likely to predominate. Other infants may have severe cyanosis on closure of the ductus arteriosus. “Tet spells” may occur with vigorous crying or dehydration: affected infants initially become hyperpneic and restless as cyanosis increases; the murmur of pulmonic stenosis softens and then disappears as pulmonary blood flow decreases; and the spell may precipitate a syncopal episode. Treatment for an acute tet spell includes putting the patient in a knee-to-chest position to increase systemic vascular resistance and administering supplemental oxygen, sedation, and a beta blocker. Ultimately, only surgical repair can provide consistent pulmonary blood flow.

Pulmonary atresia with a VSD is a more severe form of TOF that presents with severe cyanosis shortly after birth. With atresia, the prominent murmur of pulmonic stenosis characteristic of TOF is absent. If there is sufficient pulmonary blood flow from collateral vessels from the descending aorta (identified by a continuous murmur heard over the back), the patient may not require treatment with PGE1.

Neonates with pulmonary atresia and an intact ventricular septum have severe cyanosis that progresses as the ductus arteriosus closes. Patency of the ductus arteriosus is necessary for pulmonary blood flow in this lesion.

### Abnormalities of the Tricuspid Valve

With tricuspid atresia, the only outlet for blood from the right atrium is a patent foramen ovale, through which blood travels from the right to the left atrium and then to the left ventricle. From the left ventricle, blood flows via an unrestrictive VSD to the right ventricle and from there to the pulmonary artery. Tricuspid atresia may be associated with normally related or transposed great arteries. Saturation, degree of cyanosis, and blood flow depends on the relationship of the great arteries, the size of the VSD, and the presence or absence of pulmonic stenosis. If pulmonary blood flow is unobstructed, patients may have tachypnea and heart failure with minimal to no cyanosis. Physical examination is significant for an increased left ventricular impulse as opposed to other cyanotic heart diseases with an increased right ventricular impulse. A murmur may or may not be present depending upon restriction of blood flow through the VSD (a holosystolic murmur at the left lower sternal border) and the semilunar valves (a systolic ejection murmur).

Ebstein anomaly of the tricuspid valve involves the downward displacement of the valve leaflets into the right ventricular cavity. The severity of the disease is dependent on the degree of displacement and the ability of the remaining portion of the right ventricle to generate sufficient force to pump blood into the pulmonary arteries. Newborns may have massive cardiomegaly on chest radiograph, marked cyanosis, a holosystolic murmur with a gallop rhythm, hydrops,

and pulmonary artery hypoplasia. Infants with severe disease require PGE1 to maintain pulmonary blood flow until pulmonary vascular resistance has fallen and adequacy of the right ventricle and pulmonary valve can be assessed.

### Transposition of the Great Arteries

Transposition of the great arteries (TGA) is the most common cardiac lesion in neonates with cyanosis, with a male predominance. Neonates with TGA show severe cyanosis immediately after birth. There are 2 separate parallel circulations with oxygenated blood continuously circulating through the lungs and deoxygenated venous blood becoming increasingly deoxygenated as it flows through the systemic arterial circulation. Left untreated, affected neonates progress from cyanosis to tissue hypoxia, acidosis, and death. Unlike neonates with other cyanotic congenital heart lesions, these neonates have a normal volume of blood passing through the pulmonary bed. However, because their circulation is separated in parallel, neonates with TGA have very little effective pulmonary blood flow (deoxygenated blood from the systemic circulation reaching the pulmonary vascular bed) and little effective systemic blood flow (oxygenated blood that perfuses the systemic bed). The degree of mixing between the separate circulations depends on the number and size of the anatomic connections. Blood may shunt at the atrial, ventricular (if a VSD is present), or ductal level. The typical neonate with TGA and an intact ventricular septum becomes progressively more hypoxemic as the ductus arteriosus closes. Frequently, these neonates are given PGE1 until the atrial communication through the foramen ovale can be enlarged by balloon atrial septostomy performed in the cardiac catheterization laboratory or at the bedside. Clinically, the neonate with TGA is likely to appear cyanotic but otherwise healthy, with a weight appropriate for gestational age. Reverse differential cyanosis is rare but is indicative of TGA and a PDA with an associated aortic arch anomaly or pulmonary hypertension. In a neonate with TGA and an intact intraventricular septum, the chest radiograph may show a narrowed superior mediastinum with an egg-shaped cardiac silhouette (egg on a string), mild cardiomegaly, and increased pulmonary vascular markings. Surgical repair, typically by arterial switch operation, is often undertaken in the first week of life.

Truncus arteriosus is an uncommon lesion characterized by a single arterial trunk that originates from the heart and supplies the systemic, pulmonary, and coronary circulations. A large VSD is usually present, which allows total mixing of the 2 circulations. The degree of cyanosis depends on the amount of pulmonary blood flow, which is determined by the pulmonary vascular resistance and any concurrent pulmonic stenosis. Radiographs usually show cardiomegaly.

With TAPVR, pulmonary veins drain ectopically into the systemic venous circuit and ultimately into the right atrium, resulting in complete mixing of oxygenated and deoxygenated blood. The site of connection can be supracardiac, infracardiac, or cardiac. Maximal cyanosis occurs in neonates with an infradiaphragmatic connection, with pulmonary venous obstruction,

and with a small atrial communication. Auscultation of the heart may not reveal any murmurs. Chest radiographs help by demonstrating pulmonary congestion in the absence of an enlarged cardiac silhouette.

### Critical Left-Sided Obstructive Heart Lesions

Newborns with critical obstructive cardiac lesions, such as critical coarctation of the aorta, interrupted aortic arch, and HLHS, often look pale and poorly perfused and may demonstrate abnormalities in regional oxygen saturation on pulse oximetry. Hypoperfusion from insufficient flow of blood into the systemic circulation results in hypotension and, with inadequate delivery of oxygen to the tissues, progressive metabolic acidosis. With ductal-dependent systemic circulation, as the ductus arteriosus starts to close, the affected patient clinically deteriorates. With HLHS, the diminished size and function of the mitral valve, left ventricle, aortic valve, and aortic arch result in a severely diminished systemic circulation that is dependent on a widely patent ductus arteriosus to supply blood to the body. In HLHS, not only are structures distal to the ductal insertion into the aorta dependent on the ductal flow, but, given the absence of forward blood flow through the aortic valve, the coronary arteries and the right arm are also dependent on the ductus via retrograde blood flow. Closure of the ductus with HLHS often results in rapid cardiac arrest and death.

In HLHS, the  $\text{SaO}_2$  reflects mixing at the atrial level. Venous blood returning from the systemic veins mixes in the right atrium with oxygenated blood coming from the left atrium via an atrial septal defect. This mixed blood then travels through the right ventricle to the pulmonary artery and from there to the lungs and to the systemic circulation via the PDA. The measurement of  $\text{SaO}_2$  becomes crucial in this circumstance of trying to balance 2 parallel circulations. In other words, blood in the pulmonary artery of patients with HLHS can flow either into the low-resistance pulmonary vasculature or into the high-resistance systemic vasculature. An ideal saturation in this situation is about 75%, representing an approximate balance of blood flow into the lungs and into the systemic vasculature. An acute rise in saturation could represent a preponderance of blood flow into the lungs to the detriment of systemic flow, resulting in acidosis and signs of systemic hypoperfusion despite the higher  $\text{SaO}_2$ .

## CYANOSIS WITH DYSHEMOGLOBINEMIAS

Dysfunctional Hgb that is unable to bind and deliver oxygen adequately is another cause of central cyanosis. Methemoglobinemia occurs when the iron in heme is in the 3+ oxidation state and cannot bind oxygen. Most often, methemoglobinemia results from the presence of an oxidizing substance that changes Hgb  $\text{Fe}^{2+}$  to  $\text{Fe}^{3+}$ , combined with the deactivation of the usual process for reducing methemoglobin back to Hgb. The only accurate method of determining the concentration of methemoglobin is through co-oximetry.

With carbon monoxide poisoning, significant tissue hypoxia can result from the increased affinity of Hgb for carbon monoxide compared to oxygen. However, cyanosis is not usually apparent. Direct determination of oxyhemoglobin and carboxyhemoglobin saturation by means of co-oximetry can reveal the true  $\text{SaO}_2$ . Standard pulse oximeters do not accurately measure  $\text{SaO}_2$  in the presence of carbon monoxide, but special pulse oximeters are now available to determine carboxyhemoglobin saturation.

Cyanide binds to the iron of cytochrome a3, not Hgb. Thus, cyanide poisoning does not directly cause cyanosis, but results in significant tissue hypoxia from the inhibition of oxidative phosphorylation. Even with Hgb 100% saturated, a person with cyanide poisoning is not able to use the oxygen that tissues draw from the blood. At the point when sufficient tissue hypoxia makes the muscles of respiration dysfunctional, cyanosis results from hypoventilation.

### MISCELLANEOUS CAUSES OF CYANOSIS

Occasionally, children with significant gastroesophageal reflux will have paroxysmal acrocyanosis (especially perioral cyanosis) in association with brief episodes of limpness, stereotypical positioning or tonic clonic motions suggestive of a seizure, or apnea. This constellation of features is called Sandifer syndrome and often responds to treatment of the gastroesophageal reflux.

Prolonged generalized seizures are often associated with impaired respiration and can result in cyanosis if respiration ceases for a prolonged period.

Neuromuscular disorders causing weakness of respiratory muscles, such as spinal muscular atrophy, botulism, congenital myopathies, or metabolic disorders, can result in hypoventilation followed by collapse of lung units that combine to result in hypoxemia that, if severe enough can, manifest as cyanosis.

In cyanotic breath-holding spells children present with a history of crying, typically followed by sudden breath-holding in forced expiration with apnea and cyanosis. These features may progress to limpness and loss of consciousness. Cyanosis can appear faster than anticipated with simple breath-holding, and the loss of tone is often striking. As the child resumes normal breathing, the cyanosis resolves. Cyanotic breath-holding spells most commonly occur around 1 year of age with a range of 6 months to 4 years. Up to 15% of cases may have an initial episode before the age of 6 months.

### CYANOSIS IN THE NEWBORN

Acrocyanosis of the hands and feet is common in the first 6 to 24 hours of life and is usually of little significance in an otherwise well newborn. Central cyanosis persisting beyond the first few minutes of life may indicate inadequate oxygen delivery and necessitates further evaluation. Newborns can have cyanosis over the lower half of the body in the presence of right-to-left shunting across a PDA. Newborns with persistent cyanosis or hypoxemia despite oxygen administration may have CCHD, primary lung disease, or pulmonary artery hypertension.

In utero, the fetus is markedly cyanotic because the placental circulation provides blood with an  $\text{SaO}_2$  ranging from only 50% to 65% ( $\text{PaO}_2$  18–25 mm Hg). Even at this low saturation, oxygen delivery in the fetus is adequate for growth and development because of a high concentration of Hgb and the presence of fetal Hgb (Hgb F), which binds oxygen with a greater affinity than Hgb A. In utero, there is only minimal blood flow through the pulmonary artery into the lungs; instead, blood is shunted via the ductus arteriosus, the patent foramen ovale, and other anatomic channels from the right heart to the systemic circulation. At birth, with separation from the placenta and a rapid drop in pulmonary vascular resistance, blood flows from the right ventricle through the pulmonary artery and into the pulmonary capillary beds, where it is exposed to oxygen in the air. Within the first few breaths, the lungs become an extremely efficient gas exchange organ resulting in  $\text{SaO}_2$  levels sufficient for the newborn to transition from cyanotic to centrally pink. In a healthy neonate, oxygen saturations continue to rise slowly over the initial few minutes of extrauterine life. The postductal oxygen saturations are usually lower than the preductal saturations for as long as 15 minutes, indicating persistence of elevated pulmonary vascular resistance with resultant mixing of venous blood in the aorta at the level of the ductus arteriosus. In the absence of a substantial pulmonary or cardiac defect, the arterial saturation continues to rise, and simultaneously, the channels that shunt blood from right to left in utero will close. By 24 hours of age, an Hgb oxygen saturation of less than 95% in the lower extremities is abnormal and warrants further investigation.

In the period following birth, the persistence of Hgb F, with its higher affinity for oxygen, results in a leftward shift of the oxyhemoglobin dissociation curve so that cyanosis is observed only at lower oxygen tensions: 32 to 42 mm Hg, corresponding to saturations of 75% to 85%. Thus, in the presence of Hgb F, a greater degree of hypoxemia is required for cyanosis to be visible.

The best method for assessing cyanosis in a newborn is to look at the tongue. If central cyanosis persists for more than a few minutes after birth, a search for the cause should be undertaken. Comparing arterial blood saturation proximal to and distal to the entrance of the ductus arteriosus into the aorta is helpful in determining the origin of cyanosis in a newborn. In the presence of right-to-left shunting of blood through a PDA, blood in the aorta at the level of the ductal entry and more distally (left arm and lower extremities) is relatively desaturated from the admixture of venous blood entering the aorta via the PDA. In contrast, blood in the aorta proximal to the level of the PDA (right arm) will be more fully saturated because of a greater contribution of well-oxygenated blood that has returned to the left atrium and left ventricle via the pulmonary veins.

### Hyperoxia Test

In the presence of cyanosis, oxyhemoglobin desaturation, or low  $\text{PaO}_2$ , a hyperoxia test should be performed in a newborn to determine if the problem is

with pulmonary oxygenation, from an anatomic shunting of blood through the PDA, or an intracardiac lesion. In pulmonary causes of cyanosis or hypoxemia, there should be a significant increase in  $\text{SaO}_2$  and  $\text{PaO}_2$  with administration of 100% oxygen. A  $\text{PaO}_2$  of less than 100 mm Hg in an enriched-oxygen environment is a strong indicator of CCHD or PPHN, and an echocardiogram should be obtained to evaluate for congenital heart disease. With a heart lesion in which some pulmonary blood flow is present, there can be a significant increase in  $\text{PaO}_2$  or  $\text{SaO}_2$  during a hyperoxia test. A  $\text{PaO}_2$  greater than 250 mm Hg makes cyanotic heart disease unlikely, but a  $\text{PaO}_2$  of 100 to 250 mm Hg does not completely rule out CCHD and warrants further investigation. When performing a hyperoxia test, simultaneous determinations of preductal and postductal  $\text{SaO}_2$  or  $\text{PaO}_2$  should be made to delineate the presence of a right-to-left ductal shunt or other shunting pattern. If desaturation is present, and especially if there is not a significant improvement in saturation with administration of 100% oxygen, the consultation of a neonatologist or pediatric cardiologist should be sought.

### Persistent Pulmonary Hypertension of the Newborn

In PPHN, high residual pulmonary vascular resistance reduces pulmonary artery blood flow to the lungs with concomitant persistence of shunting from the right to the left side of the circulation through the ductus arteriosus and foramen ovale. This is known as persistence of fetal circulation, and the oxygen content of blood in the left atrium is decreased as a result of mixing desaturated venous blood that has crossed the foramen ovale with whatever oxygenated blood has managed to traverse the pulmonary capillary bed. The blood leaving the left ventricle becomes further desaturated when mixed with blood entering the aorta through the ductus arteriosus, having bypassed gas exchange in the lungs. With blood distal to the ductal entrance to the aorta being more desaturated than the preductal blood, the oxyhemoglobin saturation measured by pulse oximetry or ABG in the right arm may be higher than in the left arm or legs; this is known as differential oxyhemoglobin saturation or differential cyanosis.

### Newborn Screening for Congenital Cyanotic Heart Disease

Current recommendations by the American Academy of Pediatrics state that newborns should be screened by pulse oximetry prior to discharge from the newborn nursery to ascertain the possible presence of CCHD that otherwise might be missed. Studies have shown that by 24 hours of life, an oxyhemoglobin saturation of less than 95% is not normal and supportive of a cyanotic or mixing cardiac lesion. A newborn should have oxyhemoglobin saturation measured in the right arm and in 1 leg at 24 hours of life, and if there is a gradient in saturation or if the saturation is 95% or lower, an echocardiogram should be obtained prior to discharge.

## Chapter 137 DEPRESSION

Lawrence S. Wissow, MD, MPH

Symptoms of depression affect many children, including a large number whose symptoms do not rise to the level of a disorder. It is estimated that in the United States up to 3% of children younger than 13 years and up to 6% of adolescents experience depression at any given time. Estimates of lifetime prevalence of major depressive disorder (MDD) are significantly higher at up to 20%.

Depression may remit on its own or after treatment but recur spontaneously at times of developmental transitions or with new stressors (both positive and negative). Depression is among the mental health problems associated with suicidal ideation, suicide attempts, and completed suicide. Other associated problems include negative effects on school performance, early pregnancy, and impairment of function in the work, social, and family environments. Risk factors for the development of depression among children and adolescents include family history (heritability is approximately 40%), adverse childhood experiences, temperament/neuroticism, and the existence of a major nonmood disorder or a chronic or disabling medical condition. Children who seem depressed may have relatives who have also

experienced depression or other mental disorders. Finding such a history may reinforce the need to thoroughly evaluate concerns about the child, especially if there is a family history of suicide. Knowing that there are other family members who have experienced the same problems can increase empathy for the child's problems and may well provide role models for successful treatment.

There is some evidence that either initial onset or recurrence of depression may be preventable. Nurturing care during the critical first years of life, warm and confiding family relationships, learning active coping strategies for predictable stressors, promoting a sense of self-efficacy through learning to work through problems, and trying to maintain regular patterns of sleep and exercise may all be protective. If parents have mental health problems (especially depression), helping children understand and cope with changing parental mood and behavior may help prevent children themselves becoming depressed. If a child or youth has received treatment for depression, continuing treatment beyond the early stages of recovery is associated with a reduced risk of relapse or recurrence.

The guidance in this chapter applies to the care of children presenting with undifferentiated depression in pediatric clinical settings. It is based on the work of the World Health Organization, whose recommendations may be updated annually. The most up-to-date information can be found at [www.who.int](http://www.who.int).

## FINDINGS SUGGESTING DEPRESSION

Though depression may come on without an apparent trigger, even among those who seem highly successful and privileged, it can often develop after 1 or more stresses or losses, or in conjunction with prolonged anxiety. Most children and adolescents will experience an event that induces sadness, such as breakup with a friend, the death of a loved one or pet, or other losses resulting from life changes such as a move, a family member's military deployment, or parents' separation. A sadness experience of greater intensity or duration than is typical for the child's peers is a cause for concern and may indicate depression. Symptoms of depression vary. A summary of the symptoms and clinical findings that suggest depression can be found in Box 137-1. For those familiar with the symptoms of depression in adults, it is important to remember that, among children, irritability may be a more prominent symptom than sadness. In some cases, withdrawal from usual activities or decreased interaction with friends and family may be the only obvious sign, possibly coupled with a change in appetite, sleep, or level of energy. Symptoms may be elicited from either parents or youth, but ideally from both. Children and youth may be better able to report on feelings that do not result in behavior change that is obvious to others; on the other hand, children and youth may not be aware of how their appearance or behavior has changed in ways that are apparent to others. Ideally, reports should be obtained from both youth and parents if there is a suspicion of depression.

### BOX 137-1 Symptoms and Clinical Findings Suggesting Depression

#### INDICATIONS FROM HISTORY FROM YOUTH OR PARENT

- Low or sad mood present most days
- Loss of interest in school or other activities present most days
- Loss of pleasure in activities formerly enjoyed (When is last time he/you had fun?)
- Suicidal thoughts or acts
- Irritability (especially in adolescents)
- Academic difficulties
- Withdrawal from friends and family
- Physical symptoms such as headaches, abdominal pain, trouble sleeping, fatigue, or poor control of a chronic illness
- Hopelessness
- Poor concentration
- Poor or excessive sleep for developmental stage
- Weight loss (or failure to gain weight normally) or excessive weight gain
- Low self-esteem
- Loss of energy
- Agitation or slowing of movement or speech

#### RISK FACTORS FOR INCREASED SUSCEPTIBILITY

- Adverse childhood experiences (eg, mother experienced postpartum depression)
- Prior trauma or bereavement
- Family breakdown
- Shy personality
- Peer relationship problems
- Breakup of a relationship; setback or disappointment

## TOOLS TO ASSIST WITH IDENTIFICATION

Since many children do not spontaneously disclose their symptoms, standardized psychosocial screening instruments may be used to identify children with symptoms of depression. Several instruments have versions to collect information from the youth, parents, and teachers. Table 137-1 provides examples of general psychosocial screening results suggesting that a child may be depressed. Additional instruments such as the Patient Health Questionnaire for Adolescents (PHQ-A) or PHQ-A Depression Screen, Beck Depression Inventory-Primary Care (also known as Fast Screen), or the Modified Patient Health Questionnaire-9 (PHQ-9) can also be used to screen adolescents for depression or to help confirm findings of a general psychosocial screening.

It is important to differentiate the use of these tools as screening instruments at routine visits versus their use to refine concerns that have already been raised. When used as screening tools, they tend to have

**Table 137-1** General Psychosocial Screening/Results Suggesting Depression

SCREENING INSTRUMENT	SCORE SUGGESTING DEPRESSION
Pediatric Symptom Checklist (PSC)-35	<ul style="list-style-type: none"> <li>• Total score <math>\geq 24</math> for children 5 years and younger.</li> <li>• <math>\geq 28</math> for those 6–16 years.</li> <li>• <math>\geq 30</math> for those 17 years and older.</li> </ul> AND <ul style="list-style-type: none"> <li>• Further discussion of items related to depressive symptoms confirms a concern in that area.</li> </ul>
PSC-17	<ul style="list-style-type: none"> <li>• Internalizing subscale is <math>\geq 5</math>.</li> </ul> AND <ul style="list-style-type: none"> <li>• Further discussion of items related to depressive symptoms confirms a concern in that area.</li> </ul>
Strengths & Difficulties Questionnaire (SDQ)	<ul style="list-style-type: none"> <li>• Total symptom score of <math>&gt;19</math>.</li> <li>• Emotional symptom score of 7–10 (see instructions at <a href="http://www.sdqinfo.com">www.sdqinfo.com</a>).</li> <li>• Impact scale (back of form) score of 1 (medium impairment) or <math>\geq 2</math> (high impairment).</li> </ul> AND <ul style="list-style-type: none"> <li>• Further discussion of items related to depression confirms a concern in that area.</li> </ul>

relatively low sensitivity and positive predictive value. That is, positive results need further discussion to understand the meaning of the result, and negative results may not be reassuring if the parent or youth are truly concerned. When used to follow up on existing concerns, results still need discussion with families, but are more likely to be a fair indicator of the nature and severity of the child's problems. The use of a functional assessment tool such as the Strengths & Difficulties Questionnaire (SDQ) or Columbia Impairment Scale (CIS) will assist the clinician in determining whether the child's functioning is significantly impaired by the symptoms. Use of a tool to assess the impact of the child's problem on other members of the family may also be helpful; the Caregiver Strain Questionnaire (CGSQ) is one example.

## ASSESSMENT

Assessment begins by differentiating the child's symptoms from normal behavior. All children may be sad or irritable at times, but, for some children, these symptoms limit their adaptability to normal peer and family situations, interfere with learning, or precipitate suicidal thoughts. Of particular concern is major depressive disorder (MDD); *DSM-5* criteria for MDD are summarized in Box 137-2.

There are also some conditions that may mimic or co-occur with depression. Table 137-2 provides a summary of these conditions.

For a child with symptoms of depression, the psychosocial assessment process always includes determination of suicide risk, as described in Box 137-3.

## PLAN OF CARE FOR YOUTH WITH DEPRESSION

Suicidal intent is an emergency requiring immediate treatment and close supervision of the youth at all times. The care of a youth experiencing depression can begin in the primary care setting from the time symptoms are recognized, even if the youth's symptoms do not rise to the level of a disorder and

regardless of whether referral to a mental health specialist is ultimately part of the care plan.

### Engage Youth and Family in Care

Without engagement, most families will not seek or persist in care. The process may require multiple primary care visits.

Reinforce strengths of the youth and family (eg, good relationships with at least 1 parent or important adult, prosocial peers, concerned or caring family, help-seeking, connection to positive organizations) as a method of engagement and identify any barriers to addressing the problem (eg, stigma, family conflict, resistance to treatment). Use "common factors" techniques to build trust and optimism, reach agreement on incremental next steps, develop a plan of care, and collaboratively determine the role of the primary care physician. Regardless of other roles, the primary care physician can encourage a positive view of treatment on the part of the youth and family.

### Provide Psychoeducation

Depression is very common and not the result of lack of coping ability or personal strength. There is often a family history of the condition; talking about this may reduce stigma and increase empathy and a willingness to seek care, but may also be met with resistance. To assist family members in understanding the disorder, additional points to highlight include that the youth is not making the symptoms up, what looks like laziness or crossness can be symptoms of depression, and the hopelessness of depression is a symptom, not an accurate reflection of reality. However, this negative view of the world and of future possibilities can be hard to penetrate. In addition, the clinician can emphasize that treatment works, though it can take several weeks for improvement, and the affected individual is often the last person to recognize that it has taken place.

Families should be encouraged to address risk factors for maintenance of depression and for the risk of suicidal acts. Weapons should ideally be removed

**BOX 137-2 Criteria for Major Depressive Episode (DSM-5)**

- A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least 1 of the symptoms is either depressed mood or loss of interest or pleasure. **Note:** Do not include symptoms that are clearly attributable to another medical condition.
1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (eg, feels sad, empty, hopeless) or observation made by others (eg, seems tearful). **Note:** In children and adolescents, can be irritable mood.
  2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation).
  3. Significant weight loss when not dieting or weight gain (eg, a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. **Note:** In children, consider failure to make expected weight gain.
  4. Insomnia or hypersomnia nearly every day.
  5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
  6. Fatigue or loss of energy nearly every day.
  7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
  8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
  9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.
- B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The episode is not attributable to the physiologic effects of a substance or to another medical condition. **Note:** Criteria A–C represent a major depressive episode.
- Note:** Responses to a significant loss (eg, bereavement, financial ruin, losses from a natural disaster, a serious medical illness or disability) may include the feelings of intense sadness, rumination about the loss, insomnia, poor appetite and weight loss as noted in Criterion A, which may resemble a depressive episode. Although such symptoms may be understandable or considered appropriate to the loss, the presence of a major depressive episode in addition to the normal response to a significant loss should also be carefully considered. This decision inevitably requires the exercise of clinical judgment based on the individual's history and the cultural norms for the expression of distress in the context of loss.
- D. The occurrence of the major depressive episode is not better explained by schizoaffective disorder, schizophrenia, schizophreniform disorder, delusional disorder, or other specified and unspecified schizophrenia spectrum and other psychotic disorders.
- E. There has never been a manic episode or a hypomanic episode. **Note:** This exclusion does not apply if all of the manic-like or hypomanic-like episodes are substance-induced or are attributable to the psychological effects of another medical condition.

From American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Washington, DC: American Psychiatric Publishing; 2013, with permission.

from the home or secured, and a careful survey should be made for potentially lethal medications or household chemicals including pesticides. Suicidal and depressive thoughts can be spread through social networks and, increasingly, through social media. Electronic communication has been found, paradoxically, to promote isolation at the same time as it seems to be increasing connectedness. Though not often easy, parents can be helped to both monitor and limit the use of e-mail, texts, and social media posts until the child has recovered.

The clinician may also, at this point, talk about how there is a variety of treatments for depression including various forms of psychosocial care, and, for teens, medications. It may be useful to ask about what the teen and family have thought of or heard about treatment; in that way, the clinician can discover if they are anxious that the discussion is leading to a suggestion they would not be willing to accept.

### Encourage Healthy Habits

Encourage exercise, outdoor play, healthy diet, sleep, limiting screen time, 1-on-1 time with parents, praise

for positive behavior, and acknowledgment of the youth's strengths. Caring for oneself can be presented honestly as therapeutic. One can "prescribe pleasure" by telling youth and families that caring for oneself, including engaging in activities that previously were pleasurable, is not weakness but rather an important part of self-care, just as athletes need to rest or stretch in addition to testing their limits in workouts.

### Reduce Stress

Consider the youth's social environment (eg, family social history, parental depression screening, results of any family assessment tools administered, reports from child care or school). Questions to raise might include the following:

- *Are there grief and loss issues in the youth or other family members?* Grief and loss are virtually universal childhood experiences. Children vary widely in their reactions to these events, depending on their developmental level, temperament, prior state of mental health, coping mechanisms, parental responses, and support system. Also helpful can be supportive counseling; explaining to children and adolescents what

**Table 137-2** Conditions That May Mimic or Co-occur With Depression

CONDITION	RATIONALE
Sleep deprivation	Sleep problems can cause irritability and labile mood; conversely, depression may contribute to difficulty sleeping.
Somatic complaints	Depressed children may present with a variety of somatic complaints (eg, gastrointestinal symptoms, headaches, chest pain). Conversely, acute or chronic medical conditions or pain syndromes may cause depression.
Learning problems or disabilities	If symptoms of depression are associated with problems of school performance, the child may be experiencing learning difficulties. See Chapter 172, Learning Difficulty, to explore this possibility.
Exposure to adverse childhood experiences (ACE)	Children who have experienced or witnessed trauma, violence, a natural disaster, separation from a parent, parental divorce or separation, parental substance use, neglect, or physical, emotional, or sexual abuse are at high risk of developing emotional difficulties such as adjustment disorder, post-traumatic stress disorder (PTSD), and depression. Denial of trauma symptoms does not mean trauma did not occur; questions about ACE should be repeated as a trusting relationship is established. See also Chapter 129, Anxiety.
Maltreatment	Children who have experienced neglect or physical, emotional, or sexual abuse are at high risk of developing emotional difficulties such as depression; this possibility should always be considered.
Anxiety	Depression often co-occurs with anxiety. See Chapter 129, Anxiety.
Bereavement	Most children will experience the death of a family member or friend sometime in their childhood. Other losses may also trigger grief responses—separation or divorce of parents, relocation, change of school, deployment of a parent in military service, breakup with a girlfriend or boyfriend, or remarriage of parent. Such losses are traumatic. They may result in feelings of sadness, despair, insecurity, or anxiety immediately following the loss and, in some instances, more persistent anxiety or mood symptoms or disorders. Furthermore, they may make the child more susceptible to impaired functioning at the time of subsequent losses. See also the discussion of PTSD in Chapter 129, Anxiety.
Physical illness and medication side effects	Medical issues that can mimic or provoke symptoms of depression include hypothyroidism, lupus, chronic fatigue syndrome, diabetes, and anemia. Children with any chronic medical condition are more likely to experience depression than their peers (and depression may contribute to poor management of the condition). Medications commonly used in adolescence can be associated with depression (eg, acne preparations, oral contraceptives, interferon, corticosteroids).
Substance use	Children with symptoms of depression may self-medicate with alcohol, nicotine, or other drugs. Conversely, children using substances may manifest depression and deteriorating school performance. See Chapter 198, Substance Use: Initial Approach in Primary Care.
Conduct or oppositional disorders	Oppositional children may manifest depressive symptoms. Children with conduct problems are at higher risk for suicide. See Chapter 139, Disruptive Behavior and Aggression.
Psychosis	Depression can be complicated by problems with thinking that go beyond the distortions or hopelessness of low mood. These problems include delusions (ie, strongly held and usually odd false beliefs about others, one's body, or one's self), paranoia (ie, strongly felt and unjustified concerns that others are following or intend harm), or hallucinations (ie, seeing or hearing things that others don't hear or see). Individuals often don't volunteer that they are having these sorts of thoughts; asking is important if the person's interactions seem unusual. (Do you ever feel your eyes or ears play tricks on you?)
Bipolar disorder	Adults and older adolescents with bipolar disorder may have markedly varying low mood (depression) or high mood (mania), cycling over weeks or months. Diagnosis of bipolar disorder in children remains controversial. It may be considered in children who cycle through low and high moods very rapidly and in children with explosive or destructive tantrums, dangerous or hypersexual behavior, aggression, irritability, bossiness with adults, driven creativity (sometimes depicting graphic violence), excessive talking, separation anxiety, chronic depression, sleep disturbance, delusions, hallucinations, psychosis, and talk of homicide or suicide. See also Chapter 168, Inattention and Impulsivity, Chapter 139, Disruptive Behavior and Aggression, and Chapter 129, Anxiety.

they might reasonably expect; inviting them to participate in the funeral or other ceremonies to the level they feel comfortable; active listening while allowing the child or adolescent to express his or her grief; providing guidance about the grief process; and identifying and addressing feelings of guilt. When a parent is also grieving, children and adolescents may need time alone with the clinician because they may be reluctant to increase parental sadness. Providing

follow-up to see how the child and family are coping with a loss can help gauge how the family is doing and provide opportunities to assess for more serious reactions such as complicated bereavement, depression, or PTSD. Providing referral to community resources may also be helpful. The effects of profound losses, such as the death of a sibling or parent during childhood or removal from parents, last a lifetime. The clinician will need to view all future physical

**BOX 137-3 Determining Suicide Risk**

*Are there others in the family (present or past generations) who have had depression or bipolar disorder or who have attempted suicide?* Teens and parents may need opportunities to answer these questions confidentially because this is information that is not always shared among family members. Positive responses—especially a family history of suicide—increase concern. Other risk factors include substance use, a model among peers or famous individuals known to the youth, or a recent traumatic or shameful episode. A past attempt by the youth is the single strongest risk factor for future attempts and may warrant mental health referral for the current episode if the youth is not in ongoing care.

The severity of suicidal thoughts can be assessed with several questions (eg, Bright Futures, page 276) and tools (eg, SAD PERSONS; GLAD-PC). Examples include the following:

- “Have you ever felt bad enough that you wished you were dead?”
- “Have you had any thoughts about wanting to kill yourself?”
- “Have you ever tried to hurt or kill yourself or come close to hurting or killing yourself?”

- “Do you have a plan?”
- “Do you have a way to carry out your plan?”

One way of approaching suicidality is to think of your inquiry as a staged process. A significant minority of adolescents have transient suicidal thoughts or what psychiatrists call “passive death wishes”—thoughts that perhaps death would be a way out of problems or stresses but without thinking of a way to harm themselves. Absent the risk factors discussed above, these youth likely need exploration of stressors and assessment for depression or other mental health problems. A smaller group will have thought about ways of harming themselves but without a concrete plan or making any preparations. Again, absent past attempts, ongoing stressors, or substance use, these youth need support and further evaluation but are not at high risk of harming themselves. Youth with plans for harming themselves (no matter what the likelihood of success) or who have gathered or identified the means (ropes, medications, knives or other weapons) are at high risk of harming themselves. They require both a short-term plan for safety and an urgent mental health evaluation. For more information, see Chapter 191, Self-harm.

and mental health issues in the family through the prism of this loss. Overlooking such experiences and failing to follow up on the child and family’s progress after a traumatic event are lost opportunities to connect with the child and family around important mental health issues.

- *Is the youth or family experiencing unusual stress?* The family can work to try to reduce stresses and increase support for the youth. This may involve reasonable and short-term changes in demands and responsibilities, including negotiating extensions for assignments or other ways of reducing stress at school; it can also include seeking help for others in the family who are distressed. If a parent is grieving a loss or manifesting symptoms of depression, it is particularly important that the parent address his or her own needs and find additional support for the youth and other family members.
- *Are there weapons or medications in the house?* Guns should be removed from the home; other weapons, medications (including over-the-counter preparations and acetaminophen), and alcohol should be removed from the home, destroyed, or secured. In farm communities, there may be toxic products (such as insecticides or fertilizers) that may need to be secured. Depressed individuals should be dissuaded from operating dangerous machinery or engaging in other activities that require care and normal risk aversion to avoid injury.

### **Offer Initial Intervention(s) to Address the Depression Symptoms**

The strategies described in the following text are common elements of evidence-based psychosocial

interventions for depression in children and adolescents. They are applicable to the care of children with mild or emerging depressive symptoms and to those with impairing symptoms that do not rise to the level of a disorder. They can also be used as initial management of children with a depressive disorder while readying them for or awaiting access to specialty care.

*Help the youth to develop cognitive and coping skills.* Find agreement with the youth and family on a description of the problem. Many negative thoughts can be empathetically challenged and looked at from another perspective. Helpful metaphors include, “Long journeys start with a single step” and “The glass is half full, not half empty.” Relaxation techniques and visualization (eg, practicing relaxation cued by a pleasant memory, imagining being in a pleasant place) can be helpful for sleep and for anxiety-provoking situations. The clinician can also ask the youth what he or she does to feel better or relax and, if appropriate, prescribe more of that (*behavioral activation*). Encourage a focus on strengths rather than weaknesses and doing more of what the youth is good at. Distraction is also good therapy—if the youth is ruminating on a particular stressor, give permission to think about or engage with something else.

*Help the youth to develop problem-solving skills.* Determine what small achievable act would help the youth feel that he is on the way to overcoming his problems. Suggest that the youth list difficulties, prioritize them, and concentrate efforts on one issue at a time. Avoid downplaying social crises that are important to the young person even if, from an adult perspective, they seem trivial. Instead, offer to help the young person evaluate the options as he sees

them, seeking, if there is an opening, permission to offer alternatives that may not have been raised.

**Rehearse behavior and social skills.** Reactions to particular situations or people often seem to trigger or maintain low mood. If these can be identified, assist the youth in developing and practicing means of avoidance or alternative responses. Practice doing things and thinking thoughts that improve mood.

**Create a safety and emergency plan.** Developed in partnership with the family, a treatment plan includes a listing of telephone numbers to call in the event of a sudden increase in distress. This listing should be specific to the child's community and circumstances (eg, the number for a suicide or depression hotline, on-call telephone number for the practice, or area mental health crisis response team contact information). The family should also be instructed to proactively remove lethal means and monitor for suicide risk factors such as increased agitation, stressors, loss of rational thinking, expressed wishes to die, previous attempts, and comorbid conduct disorder or aggressive outbursts.

### Provide Resources

Helpful handouts and Web sites are included in Tools for Practice: Engaging Patient and Family at the end of this chapter. Provide the family with contact numbers and resources in case of emergency.

### Monitor the Youth's Progress Toward Therapeutic Goals

Child care, preschool, or school reports can be helpful in monitoring progress. Screening instruments that gather information from multiple reporters (youth, parent, teacher), such as the SDQ and PSC, can be helpful in monitoring progress with symptoms and functioning.

It is important for the clinician to work with the family to understand that it is not uncommon for treatment to be successful for a period and then seem to lose effectiveness. This can happen when there are new stresses or demands, or when, after a period of success, there has been a letup on treatment. If troubleshooting existing treatment and ways of dealing with new stresses does not help get function back to baseline, new treatments, or new diagnoses, need to be considered. In particular, as school demands increase, learning issues may need to be considered even if they were not seen as contributing problems in the past.

### Involve Specialist(s)

Involve specialist(s) if the youth does not respond to initial interventions or if indicated by the following clinical circumstances:

- A preadolescent child manifests depression or suicidal ideation.
- An adolescent with depressive symptoms has made a prior suicide attempt, developed a plan (especially with means available), or known a friend or acquaintance who has committed suicide.
- An adolescent's functioning is significantly impaired.

- Symptoms are threatening the achievement of developmentally important goals (eg, attending school or spending time with friends).
- The adolescent has mental health comorbidities such as substance use or odd behavior suggestive of an emerging psychotic disorder.
- The adolescent also has symptoms of bipolar disorder—elevated (often more driven rather than positive) mood and energy associated with irritability and behavior that seems audacious for his or her age (grandiosity).
- Depressive symptoms were preceded by serious trauma.

For youth with a diagnosis of moderate to severe MDD, data indicate superior efficacy of a combination of cognitive behavior therapy (CBT) and a selective serotonin reuptake inhibitor (SSRI) compared with either CBT alone (which may not be sufficiently helpful for these more severe cases) or an SSRI alone. Thus, youth with MDD would ideally receive treatment from a licensed therapist with training in CBT (see following text).

*When specialty care is needed, ensure that it is evidence-informed and assist the family in accessing it.* A variety of evidence-based and evidence-informed psychosocial interventions, and some pharmacologic interventions, are available for the treatment of depressive disorders in children and adolescents. Ideally, those referred for care in the mental health specialty system would have access to the safest and most effective treatments. Table 137-3 provides a summary of these interventions. Youth referred for mental health specialty care complete the referral process only 61% of the time, and a significantly smaller number persist in care. Approaches to improving the referral process include making sure that the family is ready for this step in care, that they have some idea of what the specialty care will involve, and that they understand what the physician's ongoing role may be. If the specialty appointment is not likely to occur shortly, the physician can work with the child and family on a plan to manage the problem as well as possible in the meantime.

*Reach agreement on respective roles in the youth's care.* If the youth is referred to mental health specialty care for a depressive disorder, his or her primary care physician may be responsible for initiating medication or adjusting doses; monitoring response to treatment; monitoring adverse effects; engaging and encouraging the youth's and family's positive view of treatment; and coordinating care provided by parents, school, medical home, and specialists. In fact, the youth may improve just knowing that the clinician is involved and interested. Resources available to help clinicians in these roles are provided in Tools for Practice: Medical Decision Support.

Note that not all evidence-based interventions may be available in every community. If a particular intervention is not available, this becomes an opportunity to collaborate with others in the community to advocate on behalf of children. Increasingly, states offer both telepsychiatry services and consultation/referral support "warmlines" that help physicians provide initial treatment and locate resources. The availability of the latter form of help is tracked at [www.nncpap.org](http://www.nncpap.org).

## Chapter 138

## DIARRHEA AND STEATORRHEA

Martin H. Ulshen, MD

Diarrhea, similar to vomiting, is a common symptom in young children, especially during infancy. Loosely defined, diarrhea is characterized by an increase in the frequency and water content of stools. Normal daily stool volume varies with the size of the child. Adults and older children have a normal daily stool weight up to 250 g (consisting of 60%–85% water); infants weighing fewer than 10 kg can have about 5 g/kg/day of stool. An intermediate range of 50 to 75 g/day is an appropriate approximation for the preschool-aged child. In infancy, the frequency and quality of normal stools depend very much on diet.

During the first weeks of life, breastfed infants commonly have up to 8 loose stools per day, which, at times, may contain mucus. These stools frequently follow feedings, as a result of the *gastrocolic reflex*, and do not constitute diarrhea. Infants receiving cow milk or soy formula usually have firmer and somewhat less frequent stools. After the first few weeks of life, normal breastfed infants tend to have less frequent stools, occasionally even less than once a week, although the stools remain soft. Commonly, the stool of the nursing infant becomes firm when solids or cow milk is introduced into the diet.

Steatorrhea signifies an excess of fat in the stool and is a symptom of malabsorption. However, disorders associated with malabsorption, such as gluten-sensitive enteropathy, do not always produce steatorrhea. Stools that contain an increased quantity of fat can be greasy, bulky, and foul smelling; however, with mild steatorrhea, the stool may appear normal. The stool can be evaluated quickly for fat content by using light microscopy with Sudan staining (known as qualitative analysis for stool fat). Fat excretion can be measured more precisely by quantitative chemical analysis of a 72-hour collection of stool. A record of the diet is kept during this period, and fat intake is calculated. The percentage of the ingested fat that is absorbed is called the *coefficient of absorption*.

$$\frac{\text{Fat Intake} - \text{Fat Output}}{\text{Fat Intake}} \times 100$$

Absorption of fat by infants varies with the type of fat that is fed and with the maturity of the infant. A healthy premature infant may absorb as little as 65% to 75% of dietary fat, but this amount improves to 90% in the term infant. Furthermore, neonates absorb vegetable fat much more efficiently than butterfat but human milk fat best of all. Children and adults typically absorb at least 95% of the fat in a normal diet.

## PATHOPHYSIOLOGIC FACTORS

Advances in the understanding of the pathophysiologic mechanism of diarrhea allow a more rational approach to diagnosis and treatment. Normally, the

**Figure 138-1** Ingestion, secretion, and absorption of water in the gastrointestinal tract of an adult. Numbers refer to liters of water.

gastrointestinal tract processes a large volume of fluid (Figure 138-1 lists adult data). An infant can rapidly become fluid depleted from diarrhea when such large gastrointestinal fluid shifts take place each day. Under normal circumstances, about 90% of fluid absorption takes place in the small bowel. However, the colon has a reserve capacity for fluid absorption that must be overcome before diarrhea results. In adults, the colon can reabsorb as much as 2 L of ileal fluid daily without diarrhea occurring.

Movement of water across the gastrointestinal tract mucosa is passive, following osmotic gradients created by electrolytes and other osmotically active solutes such as glucose and amino acids. Nutrients are absorbed by active transport, facilitated transport, or passive diffusion; some solutes first require digestion to simpler compounds. The flux of electrolytes across the mucosa is bidirectional. The net result of absorption and secretion of these osmotically active solutes is net water retention or loss in the stool. In this sense, diarrhea can be considered the result of either malabsorption or net secretion of osmotically active substances.

Many nutrients, including glucose and most amino acids, are absorbed by active, carrier-mediated transport, which is coupled with sodium transport. The osmotic gradient created promotes the absorption of water. Movement of water, in turn, also carries small solutes such as sodium and chloride. This process is known as *solvent drag* and appears to be an important route for sodium absorption during normal digestion. These mechanisms of sodium movement associated

with carrier-mediated nonelectrolyte transport are important to preserve normal fluid and electrolyte balance during some episodes of diarrhea (see discussion on oral rehydration).

Active absorption of chloride in exchange for bicarbonate takes place in the ileum and colon. Potassium moves passively along electrochemical gradients in the small intestine, but both active absorption and secretion of potassium occur in the colon. The permeability of the intestinal mucosa to passive fluid and electrolyte movement is high in the duodenum and proximal jejunum and decreases distally to the ileum and colon, which are poorly permeable. This feature allows the proximal intestinal contents to equilibrate rapidly with the isotonic extracellular fluid and facilitates the rapid absorption of water and small solutes by diffusion (ie, solvent drag). Conversely, the ileum and colon are poorly permeable and are able to absorb water and sodium against high electrochemical gradients.

The pathophysiologic mechanisms for diarrhea fall into 4 basic groups: osmotic diarrhea, diarrhea resulting from secretion or altered absorption of electrolytes, exudative diarrhea, and diarrhea resulting from abnormal intestinal motility. Each mechanism has unique clinical characteristics and requires a different therapeutic approach. Therefore, for the physician considering an individual patient who has diarrhea, this framework provides a rational approach for both diagnosis and treatment. Frequently, more than one mechanism of diarrhea will be involved in an episode of diarrhea, but this variation will be apparent in the evaluation.

### Osmotic Diarrhea

The ingestion of a poorly absorbable, osmotically active substance and its presence in the bowel lumen create an osmotic gradient that encourages movement of water into the lumen and subsequently into the stool. Electrolyte losses increase because electrolytes will follow water into the lumen through solvent drag and will tend not to be reabsorbed because of unfavorable electrochemical gradients.

Two main groups of poorly absorbed solutes exist, the ingestion of which result in osmotic diarrhea. The first group includes normal dietary components that may be malabsorbed either transiently or permanently. For example, disaccharides are usually hydrolyzed to monosaccharides before they are absorbed. If a mucosal disaccharidase (eg, lactase) is deficient, then the disaccharide (in this case lactose) will be malabsorbed and will represent an osmotic load that will produce diarrhea. Similarly, monosaccharides may, at times, be poorly absorbed. Medium-chain triglycerides are also osmotically active and may lead occasionally to diarrhea when ingested in high concentration, such as when infants who have compromised mucosal function are given an elemental formula containing medium-chain triglycerides. Malabsorption of long-chain triglycerides (LCTs) does not lead to osmotic diarrhea because LCTs are large hydrophobic molecules and therefore have little osmotic activity. Malabsorption of LCTs, however, may lead to secretory diarrhea, as described later in this chapter. In addition, any osmotically active solute may produce diarrhea in healthy

persons if given in quantities great enough to surpass the intestinal capacity for absorption. Thus some infants whose bowel function is normal will not tolerate the high osmolality of an elemental formula, especially if it is undiluted. Similarly, older children may develop functional gastrointestinal symptoms, including diarrhea, from ingesting large amounts of fructose in fruits and juices. Patients who have decreased mucosal surface area may have decreased functional capacity and resultant osmotic diarrhea, a problem seen in infants after small bowel resection. Protein malabsorption does not appear to be associated with diarrhea, except in the rare instance of congenital trypsinogen or enterokinase deficiency. For example, Hartnup syndrome, with its malabsorption of primary amino acids, is not associated with diarrhea.

The second group of poorly absorbed solutes includes substances that are transported in limited amounts, even by healthy individuals. This group includes magnesium, phosphates, and sulfates. Because these ions invariably lead to diarrhea when given in large enough quantities, they are used as cathartics. The introduction of lactulose in the treatment of hepatic encephalopathy takes advantage of its being a nondigestible disaccharide that leads to acidification of colonic contents by bacterial fermentation of nonabsorbed sugar. Its side effect is diarrhea. In fact, lactulose has become a popular alternative for the treatment of constipation. Sorbitol, an artificial sweetener, causes osmotic diarrhea when ingested in large quantities.

The key characteristic of an osmotic diarrhea is its association with the ingestion of the offending solute. When a patient who has an osmotic diarrhea is given no oral or enteral feeding, the diarrhea will stop dramatically within 24 hours or less. If the agent is reintroduced, as in a lactose tolerance test, the diarrhea will reappear. The diarrhea is of a moderate volume compared with that in secretory diarrhea. The sodium and potassium ion concentrations in the stool fluid are useful in establishing a diagnosis. As ileal and colonic sodium absorption continue to function against a concentration gradient, stool sodium concentration will be lower than it is in the plasma. Normally, the electrolyte concentration in the stool is roughly twice its combined sodium and potassium concentration. When this number is much less than the total stool osmolality (usually about 290 mOsm/kg), osmotically active nonelectrolytes must be in the stool, and osmotic diarrhea is present. An osmotic gap of more than 50 mOsm/kg indicates osmotic diarrhea. In some instances, the physician may be able to find the osmotic component in the stool, such as a reducing substance in lactose malabsorption.

### Diarrhea Secondary to Secretion or Altered Electrolyte Absorption (Secretory Diarrhea)

Under normal circumstances, opposing active and passive secretory and absorptive processes result in normal luminal electrolyte and water content. Secretory diarrhea occurs when a physiologic electrolyte secretory process is pathologically stimulated. Under such circumstances, a net increase in luminal electrolytes and, subsequently, a secondary increase in water occur. In addition, an associated decrease in absorptive

processes may occur. The electrolytes that have been implicated are sodium, chloride, and perhaps bicarbonate. Diarrhea also may result from a decrease in active electrolyte absorption in the absence of any change in secretory function. Distinguishing increased electrolyte secretion from decreased absorption is clinically difficult; the results are similar.

The prototype for a secretory diarrhea is cholera. Cholera enterotoxin increases intestinal secretion of chloride and inhibits the absorption of sodium by stimulating surface epithelial adenylate cyclase, leading to an increase in cellular levels of cyclic 3'5'-adenosine monophosphate. The intestinal mucosa appears normal during cholera infection, without evidence of cell necrosis, inflammation, or local bacterial invasion; and other cell absorptive functions remain normal. The normal absorption of glucose provides a route for secondary sodium absorption; as a result, oral glucose- and electrolyte-containing solutions have gained wide use in the management of cholera. A growing number of infectious agents may be associated with secretory diarrhea. Toxigenic *Escherichia coli* produces at least 2 enterotoxins that activate adenylate cyclase or guanylate cyclase. Infantile diarrhea resulting from enterotoxigenic *E coli* is well known. Other bacteria that have been associated with stimulation of intestinal secretion are strains of *Shigella*, *Salmonella*, *Yersinia*, *Klebsiella*, *Clostridium perfringens*, *Staphylococcus aureus*, and *Pseudomonas* species. Experimental work with viral enteritis suggests that this diarrhea has a significant secretory component. With rotavirus infection, secretion is the result of viral enterotoxin and only secondarily of damage to villous epithelial cells in the small intestine and repopulation of the villi with immature crypt cells.

Noninfectious causes of secretory diarrhea exist as well. Malabsorbed bile acids and long-chain fats have been shown to stimulate a colonic secretory diarrhea. Certain prostaglandins have been shown to activate adenylate cyclase and produce intestinal secretion in experimental models. Because prostaglandins are released during inflammation, researchers have hypothesized that diarrhea associated with certain inflammatory states may be caused by these hormones. This hypothesis is a particularly appealing way to explain the small bowel secretion that may take place with chronic inflammatory bowel disease. Prostaglandins have also been suggested as possible mediators for the activation of adenylate cyclase by *Salmonella* organisms in the absence of an enterotoxin. Secretory diarrhea may occur in association with increased levels of certain gastrointestinal hormones, most notably vasoactive intestinal polypeptide (VIP).

Isolated decrease of electrolyte absorption is much less frequent. The best-known example, although extremely rare, is congenital chloride-losing diarrhea. This autosomal recessive abnormality results from the apparent lack of normal, active chloride absorption by the distal small intestine. Great quantities of chloride are lost in the stool and lead to diarrhea from birth onward. A metabolic alkalosis results, in contrast to other causes of diarrhea.

The stool in secretory diarrheas tends to be watery and large in volume. Unlike osmotic diarrhea, secretory

diarrhea persists despite discontinuing oral intake. The stool electrolyte concentration (ie, twice the sum of the sodium and potassium concentrations) is about equal to the stool water osmolality because no significant osmotic nonelectrolyte component is present.

### Exudative Diarrhea

A break in the integrity of the mucosal surface of the intestine can result in water and electrolyte loss, driven by hydrostatic pressure in blood vessels and lymphatics. The exudate contains mucus, protein, and blood cells. Examples include infectious, allergic, or ulcerative colitis.

### Motility Diarrhea

The intestine has a cyclical, orderly pattern of motility. Increased, decreased, or disordered movement can lead to diarrhea. Rapid intestinal transit often occurs in association with osmotic and secretory diarrheas. Increased intraluminal volume has been implicated in stimulating increased peristaltic action. Increased motility may cause diarrhea by allowing less time for the contact of intraluminal contents with absorptive surfaces. When bowel function is compromised, as with short bowel syndrome, the time of contact with the limited functioning surface may be a crucial factor. In irritable bowel syndrome, disordered motility may also play a role. Slowed transit and severely disordered motility lead to intraluminal stasis. In the normal bowel, steady, progressive movement of chyme is one of the mechanisms that prevents the development of bacterial overgrowth, whereas stasis encourages overgrowth. Certain bacteria deconjugate bile acids in the upper small bowel and produce fat malabsorption. In addition, bacterial proteases may damage the small bowel surface. Stasis may result from an anatomic obstruction, as well as from functional motor disorders. Disordered motility frequently is an associated factor in chronic inflammatory bowel disease. Stools associated with motility diarrhea, except those secondary to fatty acid malabsorption, tend to be small in volume. The response to feeding is variable, and the gastrocolic reflex may be heightened. Patients who have chronic inflammatory bowel disease may find that meals stimulate intestinal activity, resulting in postprandial abdominal cramps and bowel movements.

## ACUTE DIARRHEA

Acute diarrhea is common in children, is transient and usually self-limited, and is caused most often by infection. In the United States, children in the first few years of life average 1 or 2 episodes per year. For most diarrheal infections, the incidence is greatest before 4 years of age. The role of the physician is to rule out causes that require specific treatment, to advise parents in supportive management, and to provide follow-up for possible complications. Box 138-1 lists some of the more frequent causes of acute diarrhea categorized by the usual presentation with or without gross blood in the stool. Transmission of diarrheal organisms is commonly by food, water, person-to-person spread, or exposure to animals at home, fairs, and petting zoos. Child care centers are likely sites for the spread

**BOX 138-1 Causes of Acute Diarrhea****USUALLY WITHOUT BLOOD IN STOOL**

- Viral enteritis rotavirus, orbivirus, noroviruses, other caliciviruses, enteric adenovirus, astrovirus, sapoviruses
- Enterotoxin *E coli*, *Klebsiella* organisms, cholera, *C perfringens*, *Staphylococcus* organisms, *Bacillus cereus*, and *Vibrio* species
- Parasitic *Giardia*, *Cryptosporidium*, *Cyclospora*, *Dientamoeba fragilis*, and *Blastocystis hominis* organisms
- Extraintestinal infection otitis media and urinary tract infection
- Antibiotic-induced and *C difficile* toxin (without pseudomembranous colitis)

**COMMONLY ASSOCIATED WITH BLOOD IN STOOL**

- Bacterial *Shigella*, *Salmonella*, and *Campylobacter* organisms, *Yersinia enterocolitica*, invasive *E coli*, gonococcus (venereal spread), enteroadherent *E coli*, enteroaggregative *E coli*, *Aeromonas hydrophilia*, and *Plesiomonas shigelloides*
- Cytomegalovirus (especially in immunocompromised individuals)
- Amebic dysentery, *Trichuris trichiura* (whipworm)
- Hemolytic uremic syndrome (enterohemorrhagic *E coli*—*E coli* O157:H7 and other Shiga toxin-producing *E coli*)
- Henoch-Schönlein purpura
- Pseudomembranous enterocolitis (*C difficile* toxin)
- Ulcerative or granulomatous colitis (acute presentation)
- Necrotizing enterocolitis (neonates)

of enteric pathogens. Pathogens that have been associated with epidemics include *Giardia lamblia*, rotavirus, *Norovirus*, *Shigella*, *Campylobacter*, *Cryptosporidium*, and *C difficile* organisms.

**Neonatal Diarrhea**

Neonates with acute diarrhea must be considered differently from older infants and children because of both lower tolerance to the associated fluid shifts and the greater likelihood of severe infection or of a congenital anomaly. In addition, signs of necrotizing enterocolitis, including gastric retention (frequently bilious), distention, and occult or bright red blood in the stool, should raise concern. Although this disease usually occurs in premature infants, it also has been reported in full-term infants. The presence of pneumatosis intestinalis, gas in the portal vein, or free intraperitoneal gas seen on abdominal radiographs supports this diagnosis. Epidemics of diarrhea associated with rotavirus, enteropathogenic *E coli*, salmonellae, and other organisms, including *Klebsiella* organisms, have been reported in nurseries. If the onset of diarrhea is associated with initial feedings, then the physician should consider congenital digestive defects, especially sugar intolerance. Hirschsprung disease may produce acute diarrhea and enterocolitis

in the neonatal period and should be considered, especially in the infant who has not passed meconium in the first 24 hours. Bloody diarrhea that results from cow milk or soy protein intolerance may develop as early as the first few days of life. Resolution and exacerbation on removal and reintroduction of cow milk or soy formula, as well as an atopic family history, are clues to the diagnosis.

**Differential Diagnosis in the Older Infant and Child**

Most episodes of acute diarrhea are transient and benign. On the initial visit, the physician must evaluate the course in terms of both possible causes and the status of hydration. The diarrhea is usually the result of viral enteritis, typically occurring with low-grade fever, vomiting, and frequent watery stools. Generally, the stools are without blood or white blood cells. Enterotoxin-producing organisms (eg, toxigenic *E coli*) are associated with watery stools and are without evidence of mucosal invasion (no high fever or blood in the stool). *G lamblia* produces watery diarrhea associated with intestinal gas and crampy abdominal pain. Diarrhea in association with extraintestinal infections, most notably otitis media and pyelonephritis, has been called *parenteral diarrhea*; its mechanism is obscure. An associated viral enteritis may occur in some cases of otitis media. Certain antibiotics, especially ampicillin, have been associated with transient diarrhea. Less common but of greater danger is antibiotic-associated pseudomembranous colitis, which may occur acutely or as a more chronic illness of 1 or 2 months' duration. *C difficile* toxin, the cause of most cases of pseudomembranous colitis, may also be associated with chronic childhood diarrhea in the absence of colitis.

The presence of blood in the stool, especially with symptoms of colonic involvement (tenesmus, urgency, and crampy lower abdominal pain), should make the physician think of infection with *Campylobacter*, *Shigella*, or *Salmonella* organisms or with *C difficile* toxin-associated pseudomembranous colitis. The symptoms of dysentery may be less striking with *Salmonella*. When the *Shigella* is an enterotoxin-producing organism, watery diarrhea may actually precede the onset of dysentery.

Patients who have *Shigella* organisms tend to appear severely ill and may have meningismus or seizures. The stools tend to be foul smelling. Up to 40% of individuals who have Guillain-Barré syndrome have evidence of a *Campylobacter* infection occurring before the onset of neurologic symptoms. *Yersinia enterocolitis* also may be associated with blood in the stool, but *Yersinia* appears to be incriminated less commonly as an etiologic agent in the United States. *E coli* can produce diarrhea by several pathogenic mechanisms; the enteroadherent, enteroinvasive, enterohemorrhagic, and enteroaggregative forms can all be associated with blood in the stool. Hemolytic uremic syndrome is the result largely of enterohemorrhagic *E coli* (especially Shiga toxin-producing *E coli* O157:H7) and less commonly *Shigella* infections.

Amebiasis is unusual in the United States, but *Entamoeba histolytica* can produce a picture of acute colitis. Causes of bloody diarrhea that are not obviously

infectious include intussusception and immune deficiencies. Chronic inflammatory bowel disease can produce an initial episode of acute dysentery, although the history may reveal previous episodes; arthralgia or growth failure may have preceded the diarrhea. A history of recent similar diarrheal illness in family members or friends suggests an infectious diarrhea.

Food-borne spread of organisms or toxins is an important cause of acute diarrheal illness. Improperly prepared poultry and eggs are the major source for both campylobacteriosis and salmonellosis, and the major source for *E coli* O157:H7 infection is ground beef. Preventive measures include safe food-handling practices, pasteurization of in-shell eggs, and irradiation of ground meat and raw poultry. Explosive diarrhea after ingesting seafood is likely from infection with *Vibrio* species. Outbreaks of norovirus have occurred on cruises ships as well as college campuses. The most common pathogens causing food-borne illness are listed in Box 138-2.

### Evaluation

At the initial evaluation (Box 138-3), the physician should establish the quantity of the diarrhea, the child's ability to maintain oral intake, and the presence of associated vomiting. On physical examination, the state of hydration should be estimated. The presence of tears and saliva is usually evidence of adequate hydration, but the most reliable reassurance comes from a normal heart rate and a brisk capillary refill. A simple guideline to hydration is that the absence of tears and the presence of a dry mouth suggest 5% dehydration; the addition of sunken eyes, sunken fontanelle, and poor skin turgor suggests 10% dehydration. Shock indicates at least 15% dehydration. In the presence of hypernatremia, the state of dehydration is typically more severe than suggested on physical examination inasmuch as extracellular fluid volume tends to be preserved at the expense of intracellular volume. A recorded weight is essential; it can be compared with previous weights and will also be available to reevaluate the state of hydration during the illness. Information about the frequency and quantity of urination is important. A history of good urine output is reassuring. Parents may underestimate or overestimate urine output (frequency and volume), especially when urine becomes mixed with liquid stool.

A stool culture should be obtained if blood or leukocytes are noted in the stool and the child is severely ill. Examination of the stool for leukocytes is helpful in establishing the presence of colitis. In the presence of both infectious and noninfectious colitis, white blood cells (WBCs) are usually found in high numbers, frequently in sheets. Polymorphonuclear leukocytes usually account for at least 60% to 80% of the cells; the presence of only occasional cells is considered a negative finding. The absence of WBCs in grossly bloody diarrheal stool occurs with enterohemorrhagic *E coli* infection but should also direct attention to entities such as intussusception and Meckel diverticulum when these diagnoses seem clinically appropriate. Amebic colitis also may not be associated with WBCs in the stool, although the trophozoites and numerous red blood cells may be visible on a saline wet mount

### BOX 138-2 Top 5 Pathogens Causing Domestically Acquired Food-Borne Illnesses (CDC 2011 Estimates)<sup>a</sup>

- *Norovirus*
- *Salmonella*, nontyphoidal
- *C perfringens*
- *Campylobacter* species
- *S aureus*

<sup>a</sup>The top five pathogens from among 31 pathogens known by the Centers for Disease Control and Prevention (CDC) to cause food-borne illness. However, unspecified agents account for 80% of the annual number of food-borne illnesses estimated by the CDC.<sup>21,22</sup>

### BOX 138-3 Evaluation of Acute Diarrhea

#### HISTORY

1. Length of illness
2. Characterization of stools: frequency, looseness (watery versus mushy), and presence of gross blood
3. Oral intake: diet, quantity of fluids and solids taken
4. Presence of vomiting
5. Associated symptoms: fever, rash, and arthralgia
6. Urine output: frequency and qualitative amount
7. Possible exposure to diarrheal illness

#### PHYSICAL EXAMINATION

1. Hydration status: weight (stable or loss), heart rate, capillary refill, mucosa (moist or dry), saliva and tears (present or absent), skin turgor (normal or poor), eyeballs and fontanelle (normal or sunken), and vital signs
2. Alertness
3. Infant: vigor of suck

#### LABORATORY (PERFORMED AS INDICATED)

1. Stool evaluation: test for viral etiology when available, culture, ova and parasites, smear for white blood cells, *C difficile* toxin assay, occult blood, and reducing substances
2. Complete blood count
3. If hydration status is in question: blood urea nitrogen (BUN) and serum electrolyte levels
4. Urinalysis
5. If child is lethargic or has had a seizure, culture for sepsis: measure the BUN and serum electrolyte and glucose levels and examine and culture the cerebrospinal fluid

preparation of the stool. Invasive bacterial diarrhea frequently is associated with a peripheral blood leukocytosis.

### Treatment

The cornerstone of treatment in acute gastroenteritis is good fluid and electrolyte management (Box 138-4).

**BOX 138-4 Fluid and Electrolyte Management of Acute Diarrhea**

- A. General rules for management of acute diarrhea
1. Oral rehydration therapy with glucose-electrolyte solution (oral rehydration solution [ORS]) is the preferred treatment of fluid and electrolyte loss, except as noted below. These solutions generally contain 25 g/L glucose (or  $\geq 30$  g/L rice starch), 45–90 mEq/L sodium, 20–25 mEq/L potassium, and 30 mEq/L bicarbonate. The higher sodium concentration is appropriate for rehydration; the lower concentration is usually adequate for rehydration with mild diarrhea and is appropriate for maintenance.
  2. Moderate to high stool output should be replaced with ORS at 10 mL/kg/stool, if losses cannot be estimated. Losses from emesis should be replaced with ORS at 2 mL/kg/episode of emesis or replace estimated losses.
  3. The use of ORS is labor intensive. If a caregiver is not available to give small amounts of fluid frequently, then intravenous therapy may be necessary. If the child is not severely dehydrated, then oral rehydration may be completed at home with close follow-up. Otherwise, intravenous fluids should include replacement of deficit, ongoing losses, and maintenance fluids. Addition of intravenous potassium should wait until urine output is established.
  4. ORS therapy is effective for hypernatremic dehydration, as well as hyponatremic and isotonic dehydration.
  5. Age-appropriate feedings should be continued during acute diarrhea, except as noted below. Formula should be offered full strength. Diet may be better tolerated if fatty foods and foods high in simple sugars (eg, undiluted juices and soft drinks) are avoided.
  6. Breastfeeding should be continued when possible.
  7. Lactose-free diet is generally unnecessary. If stools worsen on reintroduction of lactose (human milk, cow milk, or lactose-containing formula), then lactose intolerance should be considered. If stools become acid and contain reducing substances, then lactose intolerance is likely.
- B. No dehydration
1. Continue age-appropriate feeding (see A.5, A.6).
  2. Use ORS only to replace excessive stool output (see A.2).
- C. Mild-to-moderate dehydration (3%–9% of body weight)
1. Correct dehydration with 50–100 mL/kg ORS over 3–4 hours, and replace continuing losses from stool and emesis with additional ORS (see A.2). See section E for special considerations for vomiting.
  2. Reevaluate hydration and replacement of losses at least every 1–2 hours. This process may require medical supervision (emergency department, hospital outpatient unit, or physician's office).
3. Once dehydration is corrected, begin feeding (see A.5, A.6) and continue to correct losses as above.
- D. Severe dehydration (at least 10%)
1. Resuscitate with intravenous or intraosseous normal saline or lactated Ringer's solution 20 mL/kg of body weight over 1 hour. Monitor vital signs closely. Repeat until pulse and state of consciousness return to normal. Larger volumes and shorter periods of administration may be required. Delay giving intravenous potassium until urine output is established.
  2. Determine serum electrolyte levels.
  3. Lack of response to initial resuscitation suggests an underlying problem such as septic shock, toxic shock syndrome, myocarditis, cardiomyopathy, or pericarditis. Persistently poor urine output may be a sign of hemolytic uremic syndrome.
  4. ORS may be initiated when the child's condition has stabilized and mental status is satisfactory. An intravenous line should be maintained until no longer needed. See section E for special considerations for vomiting.
  5. Feeding may be restarted when rehydration is complete (see A.1, A.2).
- E. Special considerations
1. Vomiting
    - a. Vomiting occurs commonly during acute gastroenteritis.
    - b. Children who are dehydrated and vomit usually tolerate ORS.
    - c. Intractable, severe vomiting, unconsciousness, and ileus are contraindications to ORS treatment.
    - d. ORS should be started at 5 mL every 1–2 minutes.
    - e. Vomiting usually decreases as dehydration improves; larger amounts can be given at less frequent intervals.
    - f. Nasogastric tube can be used for continuous ORS infusion for persistent vomiting or feeding refusal secondary to mouth ulcers (do not use in comatose child or one who has ileus or intestinal obstruction).
    - g. Intravenous fluids should be used if ORS treatment is unsuccessful.
  2. Refusal to take ORS
    - a. Children who are not dehydrated may not take ORS because of the salty taste. However, dehydrated children generally take it well.
    - b. Giving ORS in small amounts at first allows the child to become accustomed to the taste.
    - c. ORS can be frozen in ice-pop form.

Modified from American Academy of Pediatrics Provisional Committee on Quality Improvement, Subcommittee on Acute Gastroenteritis. Practice parameter: the management of acute gastroenteritis in young children. *Pediatrics*. 1996;97:424–435; and King CK, Glass R, Bresee JS, et al. Managing acute gastroenteritis among children: oral rehydration, maintenance, and nutritional therapy. *MMWR*. 2003;52:1–16.

Commercial oral hydration solutions provide more sodium and lower carbohydrate concentration than traditional clear liquids. Human milk contains low concentrations of sodium (6–7 mEq/L); therefore, a supplemental rehydration solution should be used when diarrhea is persistent or severe.

Electrolyte content in diarrheal stool varies widely, with the highest concentrations occurring in secretory diarrheas such as cholera. Fecal sodium levels may range from 40 to 100 mEq/L and may occasionally be as high as 150 mEq/L. In rotavirus diarrhea, fecal sodium concentration is typically 20 to 40 mEq/L.

Viruses cause at least 40% to 50% of acute diarrheal illnesses in childhood. Rotavirus is becoming less common with the widespread use of vaccine; other viruses, in descending frequency, are noroviruses, astroviruses, and enteric adenoviruses. Viral enteritis has been shown to result in a transient, patchy, mucosal lesion of the small intestine, which may be associated with temporary lactose and fat malabsorption. Decreased mucosal lactase levels may be seen. In experimental viral diarrhea in piglets, intestinal glucose-stimulated absorption of sodium, and therefore water, is impaired. Rotavirus produces an enterotoxin (known as NSP4), which is of much greater importance in the production of diarrhea than virus-induced mucosal damage. Abnormal glucose absorption has also been observed in infants who have rotavirus enteritis. Nevertheless, secretion can be converted to net absorption in most children by providing oral glucose electrolyte solution because of the patchy nature of the lesion in viral gastroenteritis.

Oral rehydration solutions have been used safely and successfully to treat acute diarrhea with dehydration. Infants who have diarrhea are usually able to drink large volumes of salty-tasting liquids ad libitum appropriate for the stool output. Episodes of diarrhea in previously healthy, well-nourished children are often mild; nevertheless, the use of oral rehydration solutions to replace diarrheal loss is encouraged in infants. Liquids can be offered ad libitum, although smaller volumes per feeding may be tolerated better when diarrhea is associated with vomiting. Guidelines for rehydration are described in Box 138-4. The most recent World Health Organization recommendation is for a lower-osmolarity (245 mOsm/L) solution for rehydration (containing 75 mEq/L sodium and 75 mmol/L glucose). The contents of commercially available rehydration solutions have evolved with advances in the understanding of optimal absorption during oral rehydration; thus, the physician should consult current manufacturer specifications before choosing a product. Continuing regular feedings with supplemental oral rehydration solution is generally tolerated and thought to lead to quicker recovery. Vomiting is usually not a contraindication to oral rehydration.

Oral rehydration appears to be associated with shorter hospitalization and lower medical costs. Infants who have hypernatremic dehydration have fewer problems with seizures during oral rehydration compared with intravenous rehydration. Oral rehydration therapy, however, requires the constant

presence of a caretaker, although this individual need not have previous medical experience. The use of starches, amino acids, and probiotics in oral maintenance or rehydration solution to improve sodium and water absorption has been considered.

Indications for medications in the treatment of acute gastroenteritis in infants and children are limited. As already noted, the key mechanisms involved are intestinal secretion and transient malabsorption; physiologically, no apparent rationale exists for medications that slow gut motility (diphenoxylate, loperamide, and anticholinergics). In fact, pooling of fluid in the intestinal lumen after treatment may give a false impression that the diarrhea has improved. Slowing intestinal transit with drugs may allow greater mucosal contact with pathogens and thereby allow for local mucosal invasion. Bismuth subsalicylate, which may decrease the duration of diarrhea, has been shown to be a safe adjunct to oral rehydration but is not used routinely. Antibiotics are useful in specific situations: *Shigella* dysentery, *Yersinia* or *Campylobacter* gastroenteritis, pseudomembranous colitis, *Salmonella* infections in infants younger than 6 months, and *Salmonella* infections in older patients who have enteric fever, typhoid fever, or complications of bacteremia. *Campylobacter* gastroenteritis must be identified very early for antibiotics to shorten the illness. For the individual patient, the presence of an *E coli* serotype previously labeled enteropathogenic correlates poorly with the presence of diarrhea and is not alone an indication for antibiotic treatment. *Lactobacillus* or other probiotics may be useful to prevent infectious diarrhea but are probably not effective as treatment.

Most episodes of gastroenteritis are self-limited and of short duration. Symptoms of rotavirus enteritis typically last 4 to 10 days. However, prolonged secretion of rotavirus in stool (up to 8 weeks) has been demonstrated in association with severe gastroenteritis in immunocompetent children. The current approach to treatment is to restart the previous full-strength formula and solids early after the onset of diarrhea. If diarrhea recurs on the introduction of lactose-containing formula, then the child may have transient lactose intolerance. In this situation, a lactose-free formula should be offered. (The sugar in this formula can be either sucrose or a glucose polymer.) Sugar malabsorption (see Malabsorption Syndromes) can be identified by the determination of reducing substance in the stool. (Sucrose must be hydrolyzed first with hydrochloric acid.) Transient lactose intolerance usually lasts only a week or less but can, at times, persist for months. If the degree of dehydration is 5% or greater, then use of oral rehydration solution should be instituted, if possible, in the manner presented in Box 138-4. For severe dehydration or shock, rapid intravenous administration of 10 to 20 mL/kg of isotonic fluid or colloid is required initially and may need to be repeated early. Hyponatremia and hypernatremia must be corrected slowly to prevent complications of the central nervous system. Oral solutions are better tolerated and result in fewer central nervous system complications than intravenous solutions in infants who have hypernatremia. Potassium should not be

added to intravenous fluids until adequate urine output is established. Urine specific gravity may be misleading inasmuch as kidney-concentrating ability may be poor as a result of reduced renal urea or whole-body potassium. Inability to acidify the urine during acute diarrhea occurs commonly in infants despite the presence of metabolic acidosis. This finding is thought to be caused by sodium deficiency and the resulting inadequate delivery of sodium to the distal nephron.

## CHRONIC DIARRHEA

Although chronic diarrhea occurs in children of all ages, it is most frequent and often most challenging to diagnose in infants. Both healthy and ill infants can develop diarrhea in response to a variety of stresses. The younger the infant is, the more likely he or she will be to enter the cycle of diarrhea and secondary malnutrition that leads to further diarrhea, malnutrition, and susceptibility to infection (known as protracted diarrhea of infancy). Many of the causes of chronic diarrhea may appear at any time during childhood. Certain diseases, however, occur more commonly in infancy; others are more likely to begin in later childhood. Dividing the causes of diarrhea between infancy and older childhood is arbitrary because the groups overlap, but this method is a helpful guide in initiating the evaluation of the child who has chronic diarrhea (Box 138-5).

### Infants

The physician confronted with an infant who is reported to have chronic diarrhea must decide first whether the stool pattern is abnormal. A nursing mother who has not been forewarned may become concerned about the appearance and frequency of her child's transitional stools. The infant's weight gain and healthy appearance, combined with an explanation about stools of breastfed infants, should dispel these concerns.

In the latter half of the first year and in the second year, the most common cause for persistent diarrhea is chronic nonspecific diarrhea (also called *toddler's diarrhea*). Affected infants and toddlers have intermittent loose stools for no apparent reason. In many instances, the stools occur early in the day and typically not overnight. These children appear healthy and are thriving according to weight and length growth curves, unless inappropriate treatment with clear fluids has led to caloric deprivation. This condition represents a stool pattern rather than a pathologic state and requires minimal or no laboratory evaluation. Symptoms may begin initially after an apparent acute enteritis (postinfectious irritable bowel).

Treatment may include restricting the frequency of feedings, whether liquids or solids, in an effort to decrease stimulation of the gastrocolic reflex (in the toddler, 3 meals and a bedtime snack with nothing by mouth in between); restricting the volumes of fluids ingested when excessive; avoiding excessive intake of juices; and reassuring the parents of the benign nature of this entity. A high-fat diet may be helpful in some children, although probably is of less importance.

## BOX 138-5 Causes of Chronic Diarrhea

### COMMON CAUSES

- Chronic enteric infection: *Salmonella* organisms; *Yersinia enterocolitica*; *Campylobacter*, *Giardia*, *Cryptosporidium*, and *Cyclospora* organisms; *C difficile* toxin; enteroadherent *E coli*; rotavirus (in immunodeficient patients); cytomegalovirus; adenovirus; and HIV
- Food allergy
- Chronic nonspecific diarrhea (toddler's diarrhea, irritable colon of childhood); postinfectious irritable bowel
- Disaccharide intolerance
- Chronic constipation with overflow diarrhea
- Cystic fibrosis
- Celiac disease (gluten-sensitive enteropathy)
- Inflammatory bowel disease: Crohn disease and ulcerative colitis
- Hirschsprung disease
- Immunodeficiency states
- Monosaccharide intolerance
- Eosinophilic (allergic) gastroenteritis
- Short bowel syndrome
- Urinary tract infection
- Postenteritis bile acid malabsorption
- Factitious causes

### LESS COMMON CAUSES

- Autoimmune enteropathy
- Hormonal: adrenal insufficiency and hyperthyroidism
- Vasoactive intestinal polypeptide-secreting tumor
- Neural crest tumor and carcinoid
- Intestinal lymphangiectasia
- Acrodermatitis enteropathica
- Intestinal stricture or blind loop
- Pancreatic insufficiency with neutropenia
- Trypsinogen or enterokinase deficiency
- Congenital chloride-losing diarrhea
- Congenital sodium-secretory diarrhea
- Abetalipoproteinemia
- Microvillus inclusion disease
- Tufting disease
- Immunodysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX)
- Intestinal pseudoobstruction
- Ileal bile salt receptor defect
- Congenital disorders of glycosylation

Cholestyramine (2 g by mouth 1 to 3 times daily) is also effective at times; however, the duration of use should be restricted because of the potential for interference with fat-soluble vitamin absorption. In any event, this condition is self-limited and typically resolves by 3.5 years of age. The only danger is that well-intentioned parents may restrict oral intake to clear liquids repeatedly in an effort to treat the child; this action may result in poor weight gain. Bile acid

malabsorption is an occasional sequela of gastroenteritis that can produce persistent, watery diarrhea. This condition also will respond to cholestyramine therapy.

### **Protracted Diarrhea of Infancy**

The syndrome of protracted diarrhea of infancy is poorly understood, probably representing the final pathway for multiple causes, including gastrointestinal infections and, perhaps, food intolerances. This condition is defined somewhat arbitrarily as occurring in infants younger than 3 months and persisting for more than 2 weeks. Historically, this syndrome, previously called intractable diarrhea of infancy, has been associated with a high mortality from irreversible diarrhea and related malnutrition. However, the outcome has improved markedly with the advent of elemental diets and total parenteral nutrition. Now, intractable diarrhea is rare and related to more specific causes, such as microvillus inclusion disease.

Generally, malnutrition develops and, in concert with the protracted diarrhea, leads to alteration of gastrointestinal flora sometimes associated with bacterial overgrowth of the small intestine. Altered mucosal function of the small intestine and transient pancreatic insufficiency may occur with malnutrition and protracted diarrhea. Bile salts may be deconjugated as a result of bacterial overgrowth. In many instances, the initiating cause of protracted diarrhea is not found; it may likely be no longer present when the diarrhea has become chronic. The small bowel biopsy specimen may show patchy villous shortening with a decreased villus-to-crypt ratio and marked inflammation, as well as a damaged surface epithelium. However, the results of the small bowel biopsy also may be normal. Similarly, a rectal biopsy specimen may show evidence of inflammation, including crypt abscesses, or it may be normal. The presence or absence of these biopsy findings may not correlate with the severity of the clinical syndrome. Affected infants are severely malnourished and have low serum protein and hemoglobin levels. In many instances, they have had repeated treatment with oral clear liquids and peripheral intravenous fluids, all of which provide inadequate nutrient intake.

When evaluating a young infant who has protracted diarrhea, the physician must rule out causes that require urgent treatment while correcting hydration and nutrition. Rehydration is similar to the treatment of acute diarrhea, although estimating the level of dehydration accurately is difficult in the presence of malnutrition, and initial oral therapy is less likely to be successful. Stool output should be measured. If the urine is collected in a urine bag, then diapers can be weighed before and after stools to give an accurate measure of stool output. Urine specific gravity and volume may be deceptive because of poor concentration by the kidneys in the presence of malnutrition and total-body hypokalemia. The infant should be weighed at least daily.

Infection should be ruled out as a cause of diarrhea early in the evaluation. Several stools should be collected for culture, for examination for parasites, and for *C. difficile* toxin assay when indicated; blood and

urine cultures should also be ordered. Consideration of Hirschsprung disease with enterocolitis is important because infants who have this disorder are prone to perforation of the colon unless a decompression colostomy is performed. In such infants, eliciting a history of early obstipation and of the absence of stools in the first 24 hours of life is usually possible. In Hirschsprung disease, a flat plate radiograph of the abdomen may show a dilated colon with absence of air in the rectum. Toxic megacolon may also be seen in infectious colitis or in chronic inflammatory bowel disease in infancy. Air-fluid levels throughout the bowel are common in infants who have gastroenteritis, and this sign is not helpful in defining a cause. A barium enema under low pressure in the unprepared patient may show the narrow distal segment of rectum; however, this finding may not be present in neonates, and evaluation for ganglion cells on rectal biopsy is often necessary. The transition zone of Hirschsprung disease may be more obvious on a delayed radiograph (24–48 hours after the barium enema).

For a child who has chronic diarrhea and has been fed recently, the presence of reducing substance or an acid stool pH (<5.3) suggests carbohydrate malabsorption. The stool pH is not a good measure of the effect of diarrhea on total-body acid-base balance. If stool concentration of sodium and potassium minus chloride is greater than the plasma bicarbonate, then the infant is losing bicarbonate. WBCs or gross blood in the stool usually indicates colonic inflammation; occult blood in the stool suggests loss of blood across the mucosa anywhere in the gastrointestinal tract.

Nutritional rehabilitation should begin at once. The best choices are either enteral alimentation with an elemental or modular formula or total parenteral nutrition (TPN), peripheral or central. In many instances, enteral nutrition is tolerated best by the continuous-drip method, and recovery may be more rapid when enteral alimentation is used. Nevertheless, unsuccessful attempts at enteral feeding necessitate initiation of TPN therapy in some infants. Initial treatment with TPN and a gradually increasing, continuous enteral drip is a good approach to patients who do not tolerate elemental diet alone. Elemental formulas are composed of predigested components in fixed proportions; modular formulas allow the physician to vary the components. Stool output and weight gain may be measured to assess the infant's response.

During the treatment, further workup, including an upper gastrointestinal series with small bowel radiograph, barium enema, small bowel biopsy, proctoscopy, the measurement of sweat electrolytes, and other specific tests to rule out the entities noted later in this chapter, should be conducted as indicated. If disaccharidase levels are abnormal on small bowel biopsy, then disaccharides should be avoided.

### **Malabsorption Syndromes**

Infants and children who have malabsorption syndromes typically have diarrhea, steatorrhea, growth failure, or a combination of these conditions. Celiac

disease and cystic fibrosis are the most common chronic disorders that cause malabsorption in children in the United States. Steatorrhea is much more striking with cystic fibrosis, resulting from pancreatic insufficiency and secondary maldigestion. Infants with cystic fibrosis who nurse or are fed soy formula, but not cow milk formula, may exhibit protein malabsorption in the first months of life.

Although cystic fibrosis is thought of primarily as a respiratory disease, some infants and children have malabsorption and little history of respiratory symptoms; these patients typically have voracious appetites. The diagnosis must be confirmed by sweat electrolyte studies or genetic testing. Other diseases much less common than cystic fibrosis may be associated with prominent steatorrhea in early infancy, including congenital pancreatic insufficiency with cyclic neutropenia (Shwachman-Diamond syndrome), intestinal lymphangiectasia, and abetalipoproteinemia. Transient steatorrhea may follow an acute enteritis. Measurement of stool pancreatic elastase level is a useful screening test for pancreatic insufficiency.

Celiac disease (gluten-sensitive enteropathy) is now appreciated to be a much more frequent disorder than previously recognized. Presentation may occur at any age, and the manifestations may be subtle. In infancy, celiac disease becomes apparent within 1 to several months after the introduction of gluten-containing products (wheat, rye, barley) into the diet. The classic symptoms in an infant with celiac disease are irritability, loose stools, poor appetite, and poor weight gain. Vomiting may occur as well. In older children, features such as growth retardation or iron deficiency anemia may be more striking than diarrhea. In many patients, steatorrhea is not present, and results of absorptive studies such as the D-xylose tolerance test may be normal. Gluten-free dietary trials and antigliadin antibody studies may be misleading. The presence of endomysial antibody (EMA), tissue transglutaminase (tTG), or deamidated gliadin peptide (DGP) antibody in the serum is a much more reliable predictor of celiac disease. tTG has been identified as the antigen recognized by endomysial antibody. In individuals with total serum immunoglobulin A (IgA) deficiency, assay for tTG IgA, EMA, or DGP IgA is unreliable. A tTG or DGP IgG level can be measured. A diagnosis of celiac disease should be confirmed by small bowel biopsy. In the past, the diagnosis was often reconfirmed by a challenge with gluten and a repeat biopsy. Currently available antibody studies make this strategy unnecessary. Measuring endomysial IgA or tTG antibody may be useful in assessing the adequacy of a gluten-free diet or evaluating adherence to diet. *Giardia* infection can produce small bowel malabsorption that mimics celiac disease.

Carbohydrate (monosaccharide or disaccharide) intolerance may be primary or more commonly secondary to other gastrointestinal disorders. The congenital form of lactase deficiency is much less common than congenital sucrase-isomaltase deficiency, which typically appears after introduction of sucrose into the diet in solids. In carbohydrate intolerance, the extent of symptoms varies directly with the quantity of the offending sugar in the diet. Similarly, the age at

presentation varies with the age at which the sugar is introduced into the diet. Infants who have congenital sucrase-isomaltase deficiency may have diarrhea when fed formula containing glucose polymers as well. The diagnosis can be established by conducting standard sugar tolerance tests, measuring hydrogen excretion in the breath, or assaying the enzymes present in tissue obtained by a small bowel biopsy. Examination of the stool for reducing sugars is an imprecise screening test for stool carbohydrate content. A stool pH less than 5.3 is suggestive of carbohydrate malabsorption, whereas a stool pH more than 5.6 is evidence against this diagnosis. Sorbitol, a sugar substitute, as well as fructose, may produce diarrhea when ingested in large amounts, and both are present in fruits. Oral enzyme supplements are available for both lactase and sucrase deficiency.

The congenital deficiency of trypsinogen, the zymogen precursor of the pancreatic protease trypsin, has been reported to be a very rare cause of congenital diarrhea. The absence of trypsin in the stool suggests the diagnosis (in the absence of cystic fibrosis and congenital pancreatic insufficiency), but evaluation of the pancreatic proteases in the duodenal aspirate is necessary to confirm this impression. Congenital deficiency of enterokinase, the intestinal enzyme that activates trypsinogen to trypsin, appears in a similar fashion to that of congenital trypsinogen deficiency but is reversed with very small amounts of pancreatic replacement.

A recently described congenital, autosomal recessive disorder of chronic malabsorption and diarrhea has been characterized by a lack of intestinal enteroendocrine cells. This disorder is associated with a mutation of a gene (*NEUROG3*) expressing a protein required for endocrine cell development in the pancreas and intestine. Individuals with this disorder have been identified to develop glucose intolerance as well.

### Infection

Acute bacterial or viral enteritis may be an important initiator of protracted diarrhea in infancy. If the initial infection is no longer present at the time of evaluation for chronic diarrhea, then this association will be difficult to prove. Infections at distant sites, especially urinary tract infections, have also been implicated as a cause of chronic diarrhea in infancy. A urinalysis and urine culture should be obtained routinely in the evaluation of children who have chronic diarrhea. *Salmonella* enteritis is commonly associated with a chronic asymptomatic carrier state, especially in infancy. *Salmonella* infection, however, may also be associated with persistent diarrhea in infants. *Y enterocolitica* enteritis has been associated with a chronic relapsing diarrhea, although not commonly in the United States; however, the microbiology laboratory must look specifically for this organism, or it will be missed. *Campylobacter* enteritis also may have a protracted course. Persistence of either rotavirus or enteric adenovirus excretion has been identified in immunocompromised individuals; rarely, rotavirus may be present in the stool of an immunocompetent child for a prolonged period after a severe gastroenteritis. *Candida* has been described as

a rare cause of persistent diarrhea in immunocompetent individuals. However, the incidental finding of *Candida* is so common that the physician must be cautious before identifying it as the cause of diarrhea. A dramatic response to treatment for *Candida* would support this diagnosis.

### Parasites

The principal parasite that causes diarrhea in the United States is *G lamblia*, which may be associated with watery diarrhea and crampy abdominal pain and may occur in epidemic form. Stool testing for *Giardia* antigen is sensitive and has improved the ability to diagnose giardiasis. Evaluation of duodenal fluid aspirate or a small bowel biopsy is rarely necessary. Diarrhea from *Cryptosporidium* occurs in immunocompetent individuals and also can be recognized by stool antigen assay. *Cyclospora* has been introduced into the United States on contaminated fruits. *B hominis* and *D fragilis* may cause persistent diarrhea. Amebic dysentery may be indistinguishable from the colitis of inflammatory bowel disease and must be considered along with bacterial colitis before a diagnosis of inflammatory bowel disease can be made.

### Hirschsprung Disease

Hirschsprung disease is a congenital abnormality involving the submucosal and myenteric plexuses of the colon (rarely involving the small intestine) and accounts for about 25% of intestinal obstructions in newborns. Affected neonates almost invariably fail to pass meconium early and have persistent obstipation and recurrent abdominal distention. These features may be overlooked, however, and the infants may subsequently have chronic diarrhea. The diarrhea is secondary to enterocolitis, which can be a surgical emergency that demands rapid diagnosis and treatment. A barium enema in the neonate may reveal false-negative findings. Anorectal manometric examination may be helpful, but an adequate rectal biopsy specimen showing absence of ganglion cells and presence of nerve fiber hypertrophy confirms the diagnosis. Calretinin staining is useful as well. Properly performed, suction biopsy of the rectum is highly reliable.

### Food Allergy

Dietary protein hypersensitivity occurs in 6% to 8% of children during the first 5 years of life and most commonly is a hypersensitivity to cow milk protein. Food allergy is present in about 4% of the adult population. In 85% of children who have dietary protein intolerance, the symptoms resolve by 3 years of age. This entity should be considered when an infant who has chronic diarrhea has any of the following manifestations:

- Occult or gross blood in the stool (colitis)
- Protein-losing enteropathy
- Peripheral eosinophilia
- Other extraintestinal manifestations of allergy such as eczema, hives, or asthma

Continued or recurrent manifestations when the infant is fed a soy formula diet (free of cow milk) do not rule out the diagnosis, inasmuch as 30% to 50% of

children who have cow milk protein intolerance will also be intolerant to soy protein. Typically, symptoms improve when the feeding is changed to a protein hydrolysate formula, although the response to specific protein hydrolysate formulas may not be equivalent. Occasionally, an amino acid formula will be necessary.

Most food allergic reactions are IgE mediated and include immediate gastrointestinal hypersensitivity, with nausea, abdominal pain, and vomiting within 1 to 2 hours and diarrhea in 2 to 6 hours. Implicated food proteins include milk, egg, peanut, soy, cereal, and fish. Eosinophilic (allergic) gastroenteropathy is considered a mixed IgE-mediated and non-IgE-mediated disorder. It is characterized by infiltration of the stomach and intestine with eosinophils and often a peripheral eosinophilia. Symptoms include vomiting, abdominal pain, growth failure, and diarrhea (often with gross blood). Eosinophilic gastroenteropathy may respond to elimination diet, but corticosteroid treatment may be necessary. Non-IgE-mediated hypersensitivity food protein-induced enterocolitis syndrome (FPIES), which occurs most commonly in the first year of life but can occur at any age. Diet-induced proctitis causes gross blood in stool and often diarrhea in the first few days to months of life. Symptoms usually resolve within 72 hours with removal of the offending food allergen. Bloody diarrhea can develop in some infants while they are nursing; resolution may occur when cow milk is removed from the mother's diet or when a protein hydrolysate formula is substituted for nursing, suggesting an allergic basis.

### Short Bowel Syndrome

Short bowel syndrome is associated with congenital anomaly of the small intestine or follows extensive resection of the small intestine, resulting in chronic malabsorption and diarrhea. It begins most commonly in the newborn period in association with necrotizing enterocolitis or a congenital anomaly such as gastroschisis, intestinal atresia, or malrotation with secondary midgut volvulus. Recovery may be prolonged, requiring the use of TPN for the first several years of life. The factors that appear to contribute to persistence of symptoms in neonates include the cause, decreased intestinal absorptive surface, altered intestinal motility, intraluminal bacterial overgrowth (with secondary deconjugation of bile salts and hydroxylation of fatty acids), malabsorption of bile salts secondary to terminal ileal resection, and disaccharidase deficiency. Among neonates, infants with necrotizing enterocolitis or gastroschisis tend to have a more prolonged course than those with other causes of short bowel. In infants, symptoms of colitis may occur during the initiation of enteral feedings. Later in life, volvulus, trauma, and Crohn disease are the most common causes of short bowel syndrome.

### Intestinal Lymphangiectasia

Intestinal lymphangiectasia is a syndrome of dilated intestinal lymphatic vessels and is associated with protein-losing enteropathy, steatorrhea, lymphocytopenia, and chronic diarrhea. As a result of the bowel

protein loss, affected children may have hypogammaglobulinemia and hypoalbuminemia, usually with peripheral edema. Primary intestinal lymphangiectasia appears to be a developmental anomaly of unknown origin and is frequently associated with lymphatic abnormalities of the extremities. Secondary lymphangiectasia may result from chronic volvulus secondary to malrotation with malfixation of the bowel, constrictive pericarditis, tumor, lymphatic malformation, elevated right atrial pressure associated with the Fontan procedure for congenital heart disease, or any other factor that leads to obstruction of intestinal lymphatic flow. The diagnosis is suggested by a history of chronic diarrhea and poor growth and the presence of peripheral edema, hypoalbuminemia, hypogammaglobulinemia, and lymphocytopenia. The last 2 abnormalities may lead to a decreased immune defense and an increased risk for infections. A radiologic small bowel follow-through study may show generalized thickening of the intestinal folds. The diagnosis is confirmed by the presence of characteristically dilated lymphatics on a small bowel biopsy specimen. The treatment includes the dietary use of medium-chain triglycerides and avoidance of long-chain fat. Protection from and early treatment of infection also are important.

#### **Acrodermatitis Enteropathica**

Acrodermatitis enteropathica is a rare autosomal recessive disease that typically appears when breastfed infants are weaned. The infant has chronic diarrhea, intermittent vomiting, and an intractable erythematous, raw, and crusty rash, which is most prominent in the perianal and perioral regions but may be seen on the extremities. Alopecia is characteristically present, and conjunctivitis and dystrophic changes of the nails may occur. Infants who have acrodermatitis enteropathica are usually irritable and unhappy. The disorder is associated with a zinc deficiency (perhaps secondary to malabsorption) and responds dramatically to zinc salts given orally. A mutation of a gene that encodes a zinc-transporter protein has been identified in this condition. Nutritional zinc deficiency (eg, TPN without zinc supplementation or cystic fibrosis) may produce a syndrome similar to acrodermatitis enteropathica.

#### **Factitious Diarrhea**

Factitious diarrhea is undoubtedly more common than pediatricians recognize. Screening a stool specimen for laxative abuse is reasonable when an infant has persistent diarrhea that does not seem to fit any known pattern. Surreptitious administration of laxative to an infant is a symptom of the caregiver's psychosocial dysfunction; problems in other areas often become apparent during the social history. Frequently, a parent is a medically knowledgeable person (eg, nurse, laboratory technician) and often seems to prefer staying in the hospital to being at home. These parents are usually helpful to the nursing staff, often to the degree of excessive involvement in the nursing care, and are commonly described by the nurses as caring and concerned parents. The pediatrician may note that the parent seems to encourage invasive

diagnostic studies and treatment even beyond the medical plan and does not show an appropriate degree of hesitancy. A stool osmolality well below 290 mOsm/L can only occur by surreptitious dilution of stool with water. Another form of factitious diarrhea occurs among teenage girls who take laxatives surreptitiously to lose weight.

#### **Hormone-Related Diarrhea**

Adrenal insufficiency caused by either adrenogenital syndrome or adrenal hemorrhage may be associated with significant diarrhea, as may congenital thyrotoxicosis. VIP-secreting tumors of the pancreas have been reported as a rare cause of diarrhea in adults and an even rarer cause in children.

Ganglioneuroma and ganglioneuroblastoma have been associated with chronic secretory diarrhea. The tumors are usually abdominal but have also been reported in the mediastinum. Although these tumors are catecholamine secreting, prostaglandins or VIP may be the mediator of the diarrhea. A workup of the infant who has persistent, undiagnosed, secretory diarrhea should include urinary catecholamine studies, prostaglandin and VIP levels, and computed tomography scans of chest and abdomen. Even when the results of these studies are negative, the physician must strongly consider further studies if severe secretory diarrhea persists. When a tumor is found and is completely excised, the diarrhea usually resolves abruptly.

#### **Immune Disorders**

Immunodeficiency should be considered in any child who has chronic diarrhea. AIDS has become a major cause of immunodeficiency in childhood, and its first manifestation may be diarrhea. Several mechanisms of diarrhea have been described in infants and children who have AIDS. In addition to the organisms the physician usually considers in individuals who have persistent diarrhea (especially *Giardia*), cytomegalovirus, *Mycobacterium avium-intracellulare*, *Cryptosporidium parvum*, *Isospora belli*, and *Enterocytozoon bieneusi* must also be considered. Astrovirus, calicivirus, and adenovirus have been associated with diarrhea in HIV-infected individuals and may be more important than rotavirus as agents of AIDS diarrhea. HIV may be a primary pathogen in the bowel of these patients as well. Lactose intolerance occurs commonly in individuals who have AIDS, presumably occurring as a result of injury to small bowel mucosa. Pancreatic insufficiency with steatorrhea also has been noted in these patients.

The 2 major inborn disorders of immunity associated with diarrhea in early infancy are severe combined immunodeficiency and Wiskott-Aldrich syndrome. The most common primary disorder seen in later childhood is late-onset, variable hypogammaglobulinemia. Pure T-cell abnormalities (DiGeorge syndrome and other T-cell deficiencies) are also associated with diarrhea. Patients with selective IgA deficiency have an increased risk for celiac disease. Measurement of immunoglobulin levels should be a routine part of the workup of any patient who has chronic diarrhea. If

the diagnosis remains unclear, then a T-cell evaluation should be conducted. Chronic parasitic, adenovirus, or rotavirus infection can be seen with immunodeficiencies. Diarrhea in association with granulomas of the intestinal tract has been noted in chronic granulomatous disease of childhood. These children may have perianal fistulas or gastric outlet obstruction; the disorder may initially be mistaken for Crohn disease.

The physician must consider the full range of enteric infections associated with immunosuppression in children who have received organ transplants. Diarrhea may also be the presentation of tacrolimus toxicity or of lymphoproliferative disease. In bone marrow transplant recipients, graft-versus-host disease is a common cause of diarrhea as well.

### **Autoimmune Enteropathy**

Autoimmune enteropathy is a poorly understood disorder, with chronic diarrhea beginning in the first year of life, and is often associated with failure to thrive. Intestinal biopsies demonstrate villous atrophy and increased T-cell infiltrate in the lamina propria. Serum antienterocyte antibodies are identified in at least 50% of these patients. Extraintestinal autoimmune disorders (eg, diabetes mellitus, arthritis, thrombocytopenia, hemolytic anemia) are common and help make the diagnosis. Celiac disease, food allergy, and gastrointestinal infection must be ruled out. Treatment is immunosuppressive therapy, and a response confirms the diagnosis.

### **IPEX Syndrome**

Immune dysregulation, polyendocrinopathy, enteropathy, and X-linked inheritance (IPEX) syndrome exhibits a presentation similar to autoimmune enteropathy and similar biopsy findings. This disorder is the result of a mutation in the *FOXP3* gene.

### **Idiopathic Intestinal Pseudoobstruction**

Idiopathic intestinal pseudoobstruction constitutes a group of rare disorders characterized by widespread gastrointestinal dysmotility. When this syndrome occurs in early infancy, vomiting and diarrhea are often major components. Diarrhea may alternate with constipation. In older children, the presentation is frequently more insidious; a long history of constipation may precede the onset of diarrhea. Persons who have this syndrome usually have intermittent or constant abdominal distention. The syndrome is characterized by the radiographic findings of bowel dilation with disordered motility; urinary bladder dysfunction is also often present. These disorders, which can be sporadic or transmitted in an autosomal dominant fashion, can result from a visceral myopathy or neuropathy or from a combination of both. Bacterial overgrowth is an important cause of diarrhea in this disorder.

### **Microvillus Inclusion Disease**

Microvillus inclusion disease (familial enteropathy) is a rare disorder that is present from birth and causes

severe intractable secretory diarrhea with malabsorption. It is the most common cause of intractable diarrhea in the neonatal period. Affected infants have small bowel villous atrophy in the absence of crypt hyperplasia. The villous surface epithelial cells lack a normal brush border, and on electron microscopic examination, the microvilli are absent or severely abnormal. The defective enterocytes and colonocytes contain intracytoplasmic inclusions, which, in turn, contain the components of the brush border. Microvillus inclusions are not found in every enterocyte. Fecal sodium and chloride concentrations are similar to those found in serum. Several families have been identified with more than 1 child with this disorder.

### **Tufting Enteropathy**

In contrast to microvillus inclusion disease, symptoms of tufting enteropathy are not present at birth. Affected infants develop chronic watery diarrhea in the first few months of life. The name derives from a typical light microscopic *tufted* configuration of the small bowel mucosal epithelium.

### **Congenital Disorders of Electrolyte Absorption**

Congenital chloride-losing diarrhea and congenital sodium-secretory diarrhea are very rare, autosomal recessive disorders associated with maternal polyhydramnios. The small bowel mucosa is histologically normal, and absorption of other nutrients is normal. Infants with congenital chloride-losing diarrhea have persistent diarrhea resulting from absence of the normal ileal mechanism for active absorption of chloride in exchange for bicarbonate. They have acidic stools and a chronic metabolic alkalosis instead of the metabolic acidosis usually seen in chronic diarrhea. Stool chloride concentration is high, usually exceeding the sum of concentrations of sodium and potassium. The stool chloride of children who have this disorder may be in the range of 100 to 150 mEq/L, although it may be 30 to 100 mEq/L in infants. (Adult stool chloride is normally <20 mEq/L.) Although no satisfactory treatment exists, support with oral fluids and potassium chloride is recommended. Congenital sodium diarrhea is also a rare cause of watery diarrhea from birth. However, these infants are acidotic, and stool chloride concentration is not excessive. The disorder is the result of defective mucosal  $\text{Na}^+/\text{H}^+$  exchange in the small and large bowel.

### **Congenital Disorders of Glycosylation**

Congenital disorders of glycosylation exhibit in the first year of life, often with multisystem dysfunction. In addition to hepatic, neurologic, cardiac, and optic manifestations, they can be associated with chronic diarrhea or severe protein-losing enteropathy, or both. Diagnosis is suggested if levels of serum glycoproteins such as haptoglobin and transferrin are low. Screening for this diagnosis has been performed with serum transferrin isoelectric focusing.

### Infant of a Drug-Addicted Mother

Diarrhea may be a prominent manifestation of neonatal drug abstinence syndrome, and this diagnosis should be entertained in newborns who have persistent diarrhea, especially when other symptoms of neonatal drug withdrawal are present.

### Older Children

A pediatrician will see fewer older children with chronic diarrhea than they will infants, but older children are more likely to have chronic diarrhea associated with significant underlying disease compared with toddler's diarrhea in young children. As in infancy, the association of poor growth, weight loss, or other systemic manifestations suggests a serious organic cause. Older children may deny symptoms, and the true effect of the disorder may not be immediately apparent. Clues may include subtle changes in personality, diminished sense of well-being, or loss of appetite. Children may hesitate to talk about their stooling pattern, and the degree of deviation from the norm may become apparent only after improvement occurs following initiation of appropriate therapy.

Causes of diarrhea differ somewhat after infancy, although many of the causes seen in infancy, even congenital anomalies, may exhibit first in childhood and therefore must still be considered. Factors that determine the age at diagnosis include variability of presentation of signs and symptoms, parental expectations of normality, and the index of suspicion of the physician who is consulted. However, certain diseases, including inflammatory bowel disease and chronic constipation with encopresis, are much more likely to be seen in childhood than in infancy. Symptoms of celiac disease may begin at any age, and the high occurrence rate of celiac disease is now recognized. Cystic fibrosis may be associated with only mild manifestations in infancy and may be overlooked until frequent, bulky, foul-smelling stools become intolerable at home. AIDS is seen in older children, as well as in infants.

### Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) similar to that occurring in adults may be seen in children and adolescents. Stools may alternate from diarrhea to constipation. In addition, the patient may have recurrent, crampy, abdominal pain. Late-onset lactose intolerance and fructose or sorbitol ingestion are important to rule out as causes of symptoms that may mimic IBS. Symptoms of inflammatory bowel disease or celiac disease may also be mistaken at first for IBS. Standard treatment includes increased fiber in the diet and anticholinergics; the tricyclic antidepressants can be used for diarrhea-predominant IBS, under experienced supervision.

### Inflammatory Bowel Disease

The manifestations and presentation of Crohn disease and ulcerative colitis are so variable that these diseases should be considered whenever the physician

sees an older child who has chronic diarrhea. Systemic evidence of inflammation (fever, weight loss, and leukocytosis), abdominal pain, blood in the stool (gross or occult), perianal disease, anemia, or extraintestinal manifestations (arthralgia, arthritis, or erythema nodosum) are helpful in suggesting this diagnosis. Growth failure can occur with or precede other symptoms. An elevated sedimentation rate also is a clue; however, normal sedimentation rates may occur in as many as 50% of patients who have inflammatory bowel disease. Thrombocytosis and elevated C-reactive protein, both acute phase reactants, have been associated with inflammatory bowel disease as well and may be present in the absence of an elevated sedimentation rate. Suggestive signs and symptoms require evaluation, including a complete blood count, platelet count, erythrocyte sedimentation rate, serum protein levels, and possibly a stool assay for calprotectin. One would then consider imaging the small bowel by conventional contrast radiographs, computed tomography scan of the abdomen and pelvis, or MR enterography, as well as endoscopic examination of the upper gastrointestinal tract and colon with biopsy. Capsule endoscopy is useful when, despite negative radiographic and colonoscopic evaluation, a strong suggestion of small bowel Crohn disease is present. Serum antibody screening studies for IBD may be helpful in identifying the need for further evaluation for Crohn disease or ulcerative colitis, but may be misleading. Management of inflammatory bowel disease includes an array of medical, nutritional, and surgical measures.

### Chronic Constipation

Chronic constipation with overflow incontinence may be mistaken for diarrhea. A thorough history and physical examination, including a rectal examination, should make the diagnosis apparent. A large amount of stool may be palpable in the abdomen, but a hard mass of stool is usually found in the rectal ampulla. This presentation is treated in the usual fashion of chronic constipation (as noted in Chapter 134, Constipation).

#### WHEN TO REFER

- Persistent diarrhea when the workup for routine infectious causes is negative
- Steatorrhea
- Diarrhea or steatorrhea (or both), causing weight loss or failure to thrive
- Diarrhea associated with fevers, chronic anemia, or abdominal pain without an obvious explanation
- When inflammatory bowel disease is a consideration

#### WHEN TO ADMIT

- Acute or chronic diarrhea with mild to moderate dehydration that cannot be managed successfully with outpatient rehydration solution

- Dehydration greater than 10% of body weight
- Diarrhea with intractable vomiting
- Severe electrolyte imbalance, including hypernatremic dehydration or serum potassium level less than 3 mEq/L
- Laboratory evidence suggesting hemolytic uremic syndrome
- Chronic diarrhea or steatorrhea (or both) with persistent signs of malnutrition that is unresolved with outpatient management
- Severe manifestations of inflammatory bowel disease, unresponsive to routine outpatient treatment

## Chapter 139

**DISRUPTIVE BEHAVIOR  
AND AGGRESSION***Lawrence S. Wissow, MD, MPH*

Disruptive and aggressive behaviors are common among children from toddlerhood through adolescence. They may be transient, influenced by temperament and environmental factors, or they may be persistent, rising to the level of oppositional-defiant disorder (ODD) or conduct disorder (CD) and causing significant impairment in the child's and family's functioning. ODD affects 1% to 16% of children, depending on the population studied; CD affects 1.5% to 3.4%. Male-to-female ratio varies with age and diagnosis from 3.2:1 to 5:1. Some children progress from ODD to CD. They can be extremely challenging to manage and, if untreated, experience an increased risk of school failure, difficulty with legal authorities, substance abuse, and ultimately underemployment as adults. Those who go on to develop CD may be dangerous to themselves and others and, in some instances, require emergent treatment. All children manifesting disruptive or aggressive behaviors require intervention, education, support from parents and teachers, and careful monitoring.

There is accumulating evidence that some behavior problems can be prevented. Effective strategies include population-based interventions, supporting parents' mood and reducing exposure to stresses, helping parents learn to both read and help modulate infant emotions, and helping parents learn ways to stimulate and have positive interactions with their infants and

young children. As children get older, clinicians can offer anticipatory guidance about predictable parenting issues, written or online parenting materials, and referrals to parenting workshops. The Centers for Disease Control and Prevention ([www.cdc.gov/ncbddd/childdevelopment/positiveparenting/index.html](http://www.cdc.gov/ncbddd/childdevelopment/positiveparenting/index.html)) offers colorful public-domain materials for children and youth of a wide range of ages and a new "Essentials" series of video modules for parents of children 2 to 4 years of age. The American Academy of Pediatrics (AAP) has published guidelines for effective discipline.

The following guidance is based on the work of the World Health Organization (WHO), whose recommendations may be updated annually. The most up-to-date information can be found at [www.who.int](http://www.who.int).

**FINDINGS SUGGESTING DISRUPTIVE  
BEHAVIOR OR AGGRESSION**

Manifestations of disruptive behavior and aggression vary by age. In younger children, they include tantrums, defiance, fighting, and bullying. In older children and adolescents, they may include serious law breaking such as stealing, damage to property, or assault. A summary of the symptoms and clinical findings that suggest disruptive behavior and aggression can be found in Box 139-1. These may be elicited from parents, teachers, others familiar with the child, or the children or youth themselves. Children, youth, and even parents may minimize problems, and parents and teachers may be unaware of conduct problems that happen when the child is out of their direct supervision. Thus, tactful but persistent discussion and comparing notes among observers may be required to get a full picture of the child's behavioral issues.

**BOX 139-1 Symptoms and Clinical Findings Suggesting Disruptive Behavior and Aggression****INDICATIONS OF DISRUPTIVE BEHAVIOR  
AND AGGRESSION**

- In younger children, marked tantrums, defiance, fighting, and bullying.
- In older children and adolescents, serious law breaking such as stealing, damage to property, or assault.
- Repetitive, persistent, excessive aggression or defiance; behaviors out of keeping with the child's development level, norms of peer group behavior, and cultural context indicating a disorder rather than a phase or transitional disruption.
- Aggression may be impulsive and associated with intense emotional states, or it may be predatory and premeditated. It is important to distinguish which pattern of aggression the child is showing.

**BEHAVIORS CHARACTERISTIC OF OPPOSITIONAL-  
DEFIANT DISORDER (ODD)**

- Symptoms may be confined only to school, home, or the community.
- Angry outbursts.

- Loss of temper.
- Refusal to obey commands and rules.
- Destructiveness.
- Hitting.
- Intentional annoyance of others, but without the presence of serious lawbreaking.

**BEHAVIORS CHARACTERISTIC OF CONDUCT  
DISORDER**

- Vandalism.
- Cruelty to people and animals (including sexual and physical violence).
- Bullying.
- Lying.
- Stealing.
- Truancy.
- Drug and alcohol misuse.
- Criminal acts.
- All the features of ODD.

## TOOLS TO ASSIST WITH IDENTIFICATION

Because some children and parents do not spontaneously disclose their symptoms to their primary care clinician standardized psychosocial screening instruments may be used to identify children with symptoms of disruptive behavior or aggression. Several instruments have versions to collect information from youth, parents, and teachers. Table 139-1 provides examples of general psychosocial screening results suggesting that a child has disruptive behavior or aggression. Use of additional instruments, such as the Vanderbilt ADHD Rating Scale (developed for children 6–12 years of age) and the Modified Overt Aggression Scale (MOAS) (developed for adults, but sometimes used with adolescents), can help confirm findings of the initial screening; and the use of a functional assessment tool, such as the Strengths & Difficulties Questionnaire (SDQ) or Columbia Impairment Scale (CIS), will help the clinician determine whether the child is significantly impaired by the symptoms. For adolescents, consider assessing the extent of substance use. Use of a tool to assess the effect of the child's problem on other members of the family may also be helpful; the Caregiver Strain Questionnaire (CGSQ) is one example of such a tool. All of these instruments require

consideration of their results in the context of other clinical information obtained in the process of discussing the results with the child/youth and family members.

## ASSESSMENT

Assessment begins by differentiating the child's symptoms from normal behavior. All children are defiant at times, and it is a normal part of adolescence to, at times, do or at least consider doing the opposite of what one is told. A problem or disorder may be present if the behaviors interfere with family life, school, or peer relationships, or put the child or others in danger. Children with disruptive behavior or aggression tend to exhibit repetitive and excessive aggression or defiance out of keeping with developmental and social norms. The behaviors persist, rather than appearing briefly as part of adaptation to a new situation or developmental period. Aggression may be impulsive and associated with intense emotional states, or may be predatory and premeditated. It is important to distinguish which pattern of aggression the child is showing.

Some conditions, such as depression (with prominent irritability), attention-deficit/hyperactivity (ADHD), or sleep deprivation, can mimic or co-occur with

lesser degrees of disruptive behavior and aggression. Substance abuse may play a role in both minor and more severe forms of behavior problems. Having witnessed or experienced trauma, or currently living in a stressful or an anxiety-provoking situation may also provoke disruptive behavior. Table 139-2 summarizes these conditions.

In addition, perceptions of the child's symptoms may vary among caregivers or as a particular caregiver's circumstances change. A child whose behavior is perfectly acceptable in one setting may be seen as problematic in another where there are greater dangers or constraints, or where a caregiver may be experiencing other stressors. Recognizing the

**Table 139-2**

### Conditions That May Mimic or Co-occur With Disruptive Behavior and Aggression

CONDITION	RATIONALE
ADHD	This is a common comorbidity. Association of ODD and ADHD confers a poorer prognosis and children tend to be more aggressive, have more behavior problems that are more persistent, suffer peer rejection at higher levels, and have more significant academic underachievement. See also Chapter 168, Inattention and Impulsivity.
Sleep deprivation	Sleep problems can cause irritability and contribute to outbursts of anger and poor impulse control.
Learning problems or disabilities	Unidentified learning difficulties can contribute to frustration and oppositionality. If disruptive or aggressive behavior is associated with problems of school performance, the child may have a learning disability. See Chapter 172, Learning Difficulty, to explore this possibility.
Developmental problems	Children with overall intellectual or social limitations may experience frustration and poor impulse control.
Exposure to adverse childhood experiences (ACE)	Children who have experienced or witnessed trauma, violence, a natural disaster, separation from a parent, parental divorce or separation, parental substance use, neglect, or physical, emotional, or sexual abuse are at high risk of developing emotional difficulties such as adjustment disorder or post-traumatic stress disorder (PTSD) and may manifest outbursts of disruptive or aggressive behavior; this possibility should always be borne in mind because PTSD requires specific trauma-focused interventions. The clinician should tactfully explore the possibility that harsh physical or emotional punishment is related to the child's behavior problem or that tensions might escalate to that point. Denial of trauma symptoms does not mean trauma did not occur; questions about ACE should be repeated as a trusting relationship is established. See Chapter 129, Anxiety.
Bereavement	Most children will experience the death of a family member or friend sometime in their childhood. Other losses may also trigger grief responses—separation or divorce of parents, relocation, change of school, deployment of a parent in military service, breakup with a girlfriend or boyfriend, or remarriage of parent. Such losses are traumatic. They may result in feelings of sadness, despair, insecurity, anger, or anxiety immediately following the loss and in some instances, more persistent anxiety or mood problems, including PTSD or depression. In some children, such losses trigger aggressive or disruptive behavior. See also Chapter 137, Depression.
Anxiety	Many children with disruptive or aggressive behaviors have anxiety. When faced with demands that make them anxious, they use oppositional behavior to manage their anxiety or avoid the expectations that triggered their anxiety. See Chapter 129, Anxiety.
Depression or bipolar disorder	Marked sleep disturbance, disturbed appetite, irritability, low mood, or tearfulness could indicate that a child is depressed. Symptoms of depression rapidly alternating with cycles of agitation may suggest bipolar mood disorder. Common symptoms of pediatric bipolar disorder include explosive or destructive tantrums, dangerous or hypersexual behavior, aggression, irritability, bossiness with adults, driven creativity (sometimes depicting graphic violence), excessive talking, separation anxiety, chronic depression, sleep disturbance, delusions, hallucinations, psychosis, and talk of homicide or suicide. <sup>a</sup>
Substance use	All children exhibiting disruptive or aggressive behavior should be screened for substance use and abuse because drug effects or withdrawal from drugs may cause irritability and reduced self-control.
Autism spectrum disorders	Children with this developmental pattern also have problems with social relatedness (eg, poor eye contact, preference for solitary activities), language (often stilted), and range of interest (persistent and intense interest in a particular activity or subject). They often will have very rigid expectations for routine or parent promises and become anxious or angry if these expectations are not met.

ADHD, attention-deficit/hyperactivity disorder; ODD, oppositional-defiant disorder.

<sup>a</sup>About pediatric bipolar disorder: a guide for families. Child & Adolescent Bipolar Foundation Web site. [www.bpkids.org/site/PageServer?pagenameln\\_about](http://www.bpkids.org/site/PageServer?pagenameln_about). Accessed November 24, 2014

influence of context can be therapeutic by itself and can lead to development of a more holistic approach to intervention engaging the child, the primary caregiver, and others who support them.

## PLAN OF CARE FOR CHILDREN WITH DISRUPTIVE BEHAVIOR OR AGGRESSION

Suicidal or homicidal intent is an emergency requiring immediate treatment and close supervision of the youth at all times. Other emergencies may involve parents who feel that they can no longer tolerate the child's behavior, parents who have considered expelling the child from the home or feel that they could harm the child, or situations in which the child's behavior is related to past or ongoing trauma. Community social service agencies often have crisis services that may be of help in these situations and that can provide either respite care or emergency in-home intervention.

The care of a child exhibiting disruptive behavior or aggression can begin in the primary care setting from the time symptoms are recognized, even if the child's symptoms do not rise to the level of a disorder or if referral to a mental health specialist is ultimately part of the care plan.

### Engage Child and Family in Care

Without engagement, most families will not seek or persist in care. The process may require multiple primary care visits.

Reinforce strengths of the child and family (eg, good relationships with at least 1 parent or important adult, prosocial peers, concerned or caring family, help-seeking, connection to positive organizations) as a method of engagement, and identify any barriers to addressing the problem (eg, stigma, family conflict, resistance to treatment). Use "common factors" techniques to build trust and optimism, reach agreement on incremental next steps, develop a plan of care, and collaboratively determine the role of the primary care physician.

Regardless of other roles, the primary care physician can encourage a positive view of treatment on the part of the youth and family. To do this, the physician will likely have to manage visits in which strong negative emotions are expressed. Parents and youth may accuse each other of instigating problems, or make derogatory remarks about each other. Either party may express hopelessness about improving the situation, and youth, in particular, may refuse to speak or otherwise collaborate in care. Techniques for making the best of these encounters include avoiding taking sides, acknowledging the legitimacy of feelings, acknowledging the frequency with which these problems occur, reminding that strong feelings often occur when people care about each other, and offering to have separate conversations with youth and parents so as to give both a chance to be fully heard.

### Provide Psychoeducation

Families can be assured that behavior problems are common and something for which the clinician is

well-prepared to offer help. By the time families seek help, they are often discouraged and both angry and fearful of being criticized. Clinicians can help by emphasizing the great variation among children's temperament and personality, families' constantly evolving circumstances and stressors, and how these factors can combine to form challenges for any parent. Psychoeducation can often be tailored to a given situation by asking parents what they think are the causes of the child's behavior problems. Clinicians can acknowledge the validity of these beliefs and, to the extent necessary, begin to sketch out a range of other possible contributing factors that can be explored as treatment progresses. Usually, what parents are hoping to hear is a combination of reassurances that the behavior will improve over time and concrete plans that will work toward improvement in the short term.

### Encourage Healthy Habits

Encourage exercise, outdoor play, balanced and consistent diet, sleep (critically important to mental health), avoidance of exposure to frightening or violent media, limits on cell phone use and on TV and video games, positive and consistent (not punitive) experiences with parents, praise for good behavior, and reinforcement of strengths. This advice may extend to the parent; if the parent thinks that his ability to carry out normal activities is restricted by the child's behavior, it may be appropriate to see if there are ways the parent can feel more free to do routine or enjoyable activities.

### Reduce Stress

Consider the environment (eg, family social history, parental depression screening, results of any family assessment tools administered, reports from child care or school). Questions to raise might include the following:

- *Is stress on the parent(s) from causes other than the child leading to parental irritability or low mood, drinking, or greater demands for the child to behave? Are there ways for parents to get more support for themselves? Explore parents' readiness to seek and accept help.*
- *Do inconsistencies or differing beliefs about parenting among caregivers (eg, parents, grandparents) undermine attempts to create rules, limits, or consequences? Can caregivers agree on priority behavioral problems and how to address them? Explore conflicts; seek agreement on common beliefs and achievable steps to help the child.*
- *Are nonacademic issues such as the presence of bullying contributing to the behavior? Are there other social or behavioral challenges in school? Collect information directly from the school to explore these issues.*

If problems are mainly or exclusively at school, parents should request that the school assess the child for special educational needs and develop a plan to monitor behavior while at school. Primary care clinicians can often provide support in these situations by communicating to the school the degree to which the parents are actively engaged in finding help for their child's problems.

### Offer Initial Intervention(s)

The strategies described in the following text are common elements of evidence-based and evidence-informed psychosocial interventions for disruptive behavior and aggression. They are applicable to the care of children with mild or emerging problems with disruptive behavior and aggression and to the care of those with impairing symptoms that do not rise to the level of a disorder. They can also be used as initial primary care management of children with CD or ODD while readying them for referral or awaiting access to specialty care.

*Promote daily positive joint activities between parents and the child or teen.* The clinician can counsel parents to reinforce compliant, pro-social behavior using parental attention (“Catch ‘em being good” [Ed Christopher-son]). In addition, parents can encourage, praise, and reward specific, agreed-upon, and desired (target) behaviors. If appropriate, they can be monitored with a chart. Parents can negotiate rewards with the child. Change target behaviors every 2 to 6 weeks; change rewards more frequently. The choice of target behaviors and the time intervals for rewards should be developmentally appropriate. Parents can be encouraged to focus discipline on priority areas. Some minor unwanted behaviors can be ignored; often they will stop as the main focus of child-parent conflict improves. What is most important is that parents find a way to reduce the overall negative tone of interaction and find as many “successes” as possible about which to comment.

*Encourage parents to focus on prevention.* There are several ways for parents to do this. They can reduce positive reinforcement of disruptive behavior by not responding to negative bids for attention and by not engaging in discussion with the child when delivering a request or consequence. In contrast, when children seek attention in a prosocial way, parents should make every attempt to respond positively, even if the response is brief. When possible, parents can try to reorganize the child’s day to avoid situations in which the child cannot control himself. Examples include asking a neighbor to look after the child while the parent goes shopping, ensuring that activities are available for long car journeys or other potentially boring activities, and arranging activities in separate rooms for siblings who are prone to fight. In addition, parents can monitor the whereabouts of adolescents by telephoning the parents of friends whom they say they are visiting. All children appreciate age-appropriate advance notice of what will be expected of them and opportunities to make choices about how to meet those expectations.

Parents also can determine ways to limit contact with friends who have behavior problems and promote contact with friends who are a positive influence. If parents suspect the child’s behavior may be caused or exacerbated by a learning problem, they can request that the school evaluate the child for learning problems.

*Encourage parents to be calm and consistent.* The clinician can suggest the following strategies to parents:

- Set clear house rules and give short, specific commands about the desired behavior, not prohibitions

about undesired behavior (eg, “Please walk slowly,” rather than “Don’t run”).

- Prioritize issues and target only a few key behaviors until things improve. Within these areas of behavior, make initial targets easily achievable.
- Provide consistent and calm consequences for misbehavior. Consequences should not be drastic or, in the case of young children, go on for so long that the child is likely to forget what he or she originally did wrong. “Time out” should be brief (the rule of thumb for preschoolers is 1 minute per year of age); consequences for older children can involve brief loss of privileges or parental attention. Ideally, these punishments are mirrored by inverse responses for good behavior, especially more parental attention.
- Find a way for children to make reparation for a negative behavior (eg, doing something nice for a sibling they have struck, cleaning up a mess they made while in a tantrum), followed by praise.
- When enforcing a rule, avoid getting into arguments or explanations, because this merely provides additional attention for the misbehavior; defer negotiations until periods of calm.
- If the behavior is taking place in public, quietly advise the child or youth that the problem has been noted but, if possible, defer a response until home or in a less public place.
- Consider parenting classes.
- See also the suggestions in Chapter 168, Inattention and Impulsivity, including Strategies for Working Constructively With a Child’s School and Guidelines for Homework Battles.

*Create a safety and emergency plan.* When behavior problems are severe or involve threats of violence or running away, a care plan should be developed jointly with family, including a listing of telephone numbers to call for emergencies. This listing can include hotlines, the on-call telephone number for the practice, or area mental health crisis response team contact information, according to community protocol. The clinician should also instruct the family to proactively remove weapons from the home and monitor for situations that trigger outbursts.

### Provide Resources

Offer the child and parents educational resources to assist them with self-management. Helpful handouts, publications, and Web sites are included in Tools for Practice: Engaging Patient and Family. Provide the family with contact numbers and resources in case of an emergency.

### Monitor the Child’s Progress Toward Therapeutic Goals

Child care, preschool, or school reports can be helpful in monitoring progress. Screening instruments that gather information from multiple reporters (youth, parent, teacher), such as the SDQ and PSC, can be helpful in monitoring progress with symptoms and functioning.

It is important for the clinician to help the family understand that it is not uncommon for treatment to

be successful for a period and then seem to lose effectiveness. This can happen when there are new stresses or demands, or when, after a period of success, there has been a letup on treatment. If trouble-shooting existing treatment and ways of dealing with new stresses does not help get function back to baseline, new treatments, or new diagnoses, need to be considered. In particular, as school demands increase, learning issues may need to be considered even if they were not seen as contributing problems in the past.

### Involve Specialist(s)

Consider involving specialist(s) if the child does not respond to initial interventions or if indicated by the following clinical circumstances:

- Child is younger than 5 years and problems go beyond what is expected developmentally.
- Family is not able to maintain a calm, consistent, or safe environment.
- Child’s behaviors are injurious to other children or animals.
- Child has comorbid depression.
- Child is experiencing severe dysfunction in any domain.
- Child has comorbid anxiety. (The combination of shyness, anxiety, and behavior problems is thought to be particularly risky for future behavior problems of a more serious nature.)
- An adolescent has co-occurring problems with substance use.
- Problems at school are interfering with academic achievement or relationships.
- Child or adolescent is involved with legal authorities. (This situation requires coordination with probation officers and understanding the terms of probation; simply reminding the adolescent and

family of the consequences of violating probation can help promote participation in treatment or changes to lifestyle.)

*When specialty care is needed, ensure that it is evidence-informed and assist the family in accessing it.* A variety of evidence-based and evidence-informed interventions are available for the treatment of emotional problems in young children and for CD and ODD in school-aged children and adolescents. Ideally, those referred for care in the mental health specialty system would have access to the safest and most effective treatments. Table 139-3 lists programs targeting young children and their families. Table 139-4 provides a summary of interventions for children and adolescents.

Approaches to improving the referral process include making sure that the family is ready for this step in care, that they have some idea of what the specialty care will involve, and that they understand what the clinician’s ongoing role may be. If the specialty appointment is not likely to occur in the near future, the clinician can work with parents on a plan to manage the problem as well as possible in the meantime.

Note that not all evidence-based interventions may be available in every community. If a particular intervention is not available, this becomes an opportunity to collaborate with others in the community to advocate on behalf of children. Increasingly, states offer both telepsychiatry services and consultation/referral support “warmlines” that help physicians provide initial treatment and locate resources. The availability of the latter form of help is tracked at [www.nncpap.org](http://www.nncpap.org).

*Reach agreement on respective roles in the child’s care.* If the child is referred to mental health specialty care, the primary care physician may be responsible

## Chapter 140 DIZZINESS AND VERTIGO

Ruby F. Rivera, MD; Catherine R. Sellinger, MD

*Dizziness* and *vertigo*, although often used interchangeably, refer to very different symptoms that have very different clinical implications. Distinguishing these symptoms in young children may be especially difficult because much of the distinction depends on the patient's account of the history.

### DIZZINESS

#### Definition

Dizziness, a relatively common complaint in childhood and adolescence, is “an imprecise term commonly used by patients in an attempt to describe various peculiar subjective symptoms such as faintness, giddiness, light-headedness, or unsteadiness.” Patients who have simple dizziness do not describe the room spinning around them, and they do not have nystagmus.

#### Causes of Dizziness

Dizziness is commonly seen as a symptom of presyncope in children and adolescents with fever, dehydration, orthostatic hypotension, and vasovagal syncope. It is also commonly associated with anemia, either from acute or chronic blood loss or from a congenital condition such as sickle cell disease. Any heart disease or dysrhythmia that reduces cardiac output can cause dizziness; so too can hypertension. Hypoglycemia, which may be associated with altered mental status or seizures, can first manifest as dizziness. Hyperthyroidism, hypothyroidism, and Addison disease can also cause dizziness. In female adolescents, pregnancy should be considered in the differential diagnosis of dizziness. Ocular disorders such as refractive errors, astigmatism, amblyopia, and strabismus can cause dizziness. Dizziness is often a symptom of anxiety and as part of panic attacks. Dizziness may also be caused by medications

that affect the ear, such as aminoglycosides, phenytoin, loop diuretics, and nonsteroidal anti-inflammatory drugs. An algorithm to aid in narrowing the differential diagnosis of dizziness is shown in Figure 140-1.

When young children cannot describe dizziness or vertigo, observers tend to apply these terms to a child who is unsteady while standing. Disequilibrium in this age group may reflect acute cerebellar problems, such as postviral acute cerebellar ataxia and posterior fossa tumors. In adolescents, particularly girls, ataxia as part of multiple sclerosis may be described as dizziness. Another common cause of disequilibrium in young children is middle-ear disease. Several studies have shown deterioration in vestibular balance and motor function in children with middle-ear effusion. If not self-limited, symptoms usually resolve after placement of tympanostomy tubes.

## VERTIGO

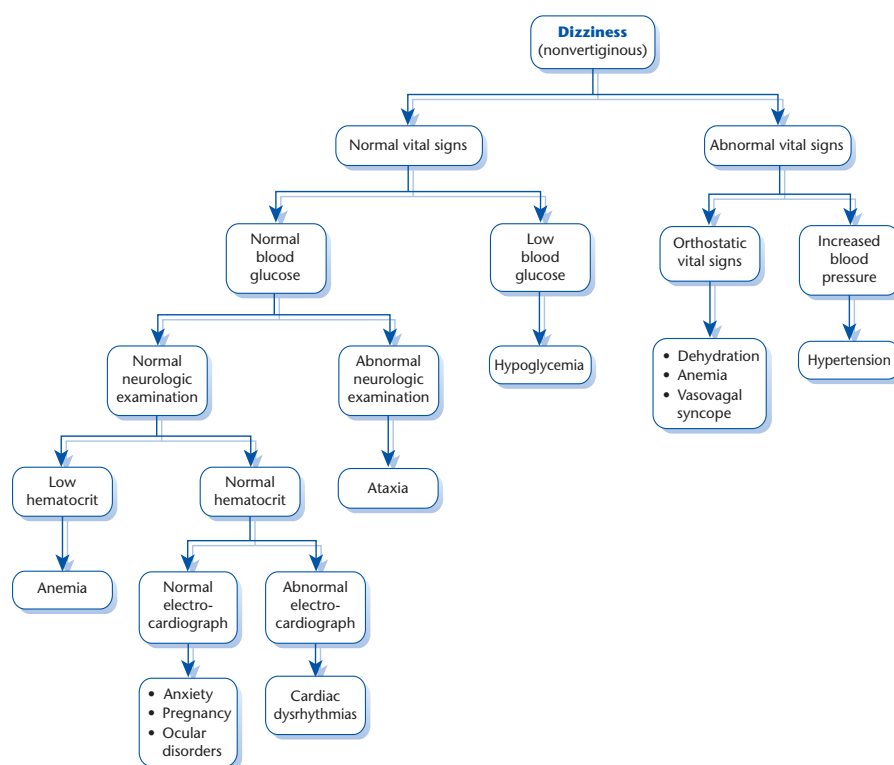

#### Definition

Vertigo is “a sensation of spinning or whirling motion. Vertigo implies a definite sensation of rotation of the subject or of objects about the subject in any plane.” True vertigo almost always is accompanied by nystagmus, at least at the time of the episode. Thus the primary care physician should ask observers about the presence of nystagmus and should ask them to watch for it in future episodes.

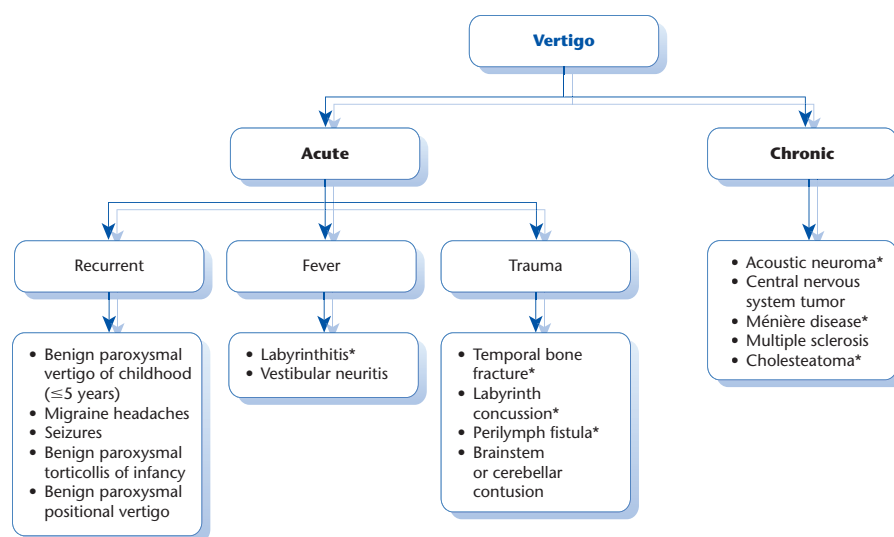

#### Causes of Vertigo

The causes of vertigo can be differentiated based on 3 elements in the history: whether the vertigo is acute or chronic, whether episodes are recurrent, and whether it is accompanied by hearing loss. The causes of vertigo in children vary greatly from those in adults. Acute episodic vertigo is the most common type encountered by pediatricians and is usually not accompanied by hearing loss (Figure 140-2).

The most common causes of acute episodic vertigo are migraine headaches and related syndromes. Benign paroxysmal torticollis of infancy is thought to be a migraine variant that begins in infancy and generally resolves spontaneously by 2 to 3 years of age. It is characterized by episodes of recurrent head tilt, which may last for hours or days and is often associated with vomiting, agitation, pallor, and ataxia. Benign paroxysmal vertigo of childhood is also considered a migraine variant and is typically seen in children younger than 5 years. These children have the sudden onset of extreme unsteadiness and inability to stand, usually with nystagmus and sometimes with vomiting. The episodes last seconds to minutes. In many cases, the family has a history of migraine headaches, and many of these patients develop more typical migraine headaches in later life. Older children and adolescents may have episodic vertigo as a result of basilar artery migraines. Affected patients often have scintillating scotomas or visual obscuration, oral paresthesias, tinnitus, and occasionally drop attacks with or without loss of consciousness. These early symptoms are commonly

**Figure 140-1** Algorithm for the differential diagnosis of dizziness.

**Figure 140-2** Algorithm for the differential diagnosis of vertigo. Asterisk denotes an associated hearing loss.

but not always followed by a pounding headache. Other causes of acute recurrent vertigo include seizures, perilymph fistula, and benign paroxysmal positional vertigo. Seizures that are associated with vertigo are followed by an alteration or loss of consciousness. A perilymph fistula is an abnormal

connection between the inner- and middle-ear spaces. Although some fistulas are congenital, most are acquired from trauma, such as direct penetrating trauma, head trauma, or barotrauma. Flying, diving, coughing, sneezing, or any type of excessive strain or exertion may tear the oval or round window,

causing a sudden onset of vertigo associated with hearing loss. Benign paroxysmal positional vertigo (BPPV), although extremely common in adults, is rare in children. BPPV is believed to be caused by otoconia (debris or *ear rocks*) that have been deposited in a sensitive location in the semicircular canal. Acute episodes of severe vertigo are precipitated by a change of head position and are associated with nystagmus, nausea, and vomiting. The Epley and Semont maneuvers attempt to relocate the otoconia into a less-sensitive location. (A helpful Web site that illustrates these maneuvers is [www.dizziness-and-balance.com/disorders/bppv/bppv.html](http://www.dizziness-and-balance.com/disorders/bppv/bppv.html)). Vestibular neuritis exhibits similar symptoms to BPPV and, although uncommon in children, should be considered if vertigo is preceded by a viral infection. Neither BPPV nor vestibular neuritis is associated with hearing loss.

Vertigo with hearing loss in childhood is usually associated with severe otitis media leading to labyrinthitis. Affected patients are acutely uncomfortable, both from ear pain and from severe vertigo, usually with nausea, vomiting, and nystagmus. Less common causes of hearing loss with vertigo in children include head trauma or ear trauma. Ménière disease, consisting of vertigo, fluctuating hearing loss, pressure in the ear, and tinnitus, is rare in young children, usually occurring after 11 years of age.

Chronic persistent vertigo, especially if accompanied by neurologic signs, is usually indicative of central nervous system disease, including tumors, acoustic neuromas (seen in neurofibromatosis type II), and demyelinating and degenerative disorders.

## EVALUATION OF DIZZINESS AND VERTIGO

### History

Most episodes of dizziness and vertigo can be diagnosed on history and physical examination. Useful information, which may lead to a particular diagnosis, is listed in Table 140-1.

### Physical Examination

On physical examination, the physician should document orthostatic vital signs, look for evidence of anemia or dehydration, and pay particular attention to the head, neck, cardiac, and neurologic findings. The Dix-Hallpike maneuver (Nylan-Barany test) can help localize the source of nystagmus or vertigo. To provoke an episode, the child is moved rapidly from a sitting to supine position with the head 45 degrees below the edge of the table and turned 45 degrees to 1 side. The ear that is facing the floor when the nystagmus is elicited is the affected side. Nystagmus that resolves when the child fixates on an object is suggestive of a peripheral or vestibular disease, as opposed to persistent nystagmus, which is seen in central nervous system disorders.

The ears are examined for vesicles of herpes zoster (Ramsay-Hunt syndrome); a distorted tympanic membrane may be seen with otitis media, cholesteatoma, and perilymph fistula. Two useful maneuvers that may

**Table 140-1**

### Differential Diagnoses of Dizziness and Vertigo

INFORMATION	POSSIBLE DIAGNOSES
<b>FAMILY HISTORY</b>	
Neurofibromatosis	Acoustic neuroma
Seizure disorder	Seizure
Migraines	Benign paroxysmal torticollis of infancy
	Benign paroxysmal vertigo of childhood
	Migraine
	Dysrhythmias
Unexplained syncope or sudden cardiac death	
Anxiety, panic disorders	Anxiety
<b>MEDICATION HISTORY</b>	
Aminoglycosides, loop diuretics, phenytoin, nonsteroidal anti-inflammatory drugs, chemotherapeutic agents, quinine	Ototoxicity
	Intoxication
<b>MEDICAL HISTORY</b>	
Acute or chronic blood loss	Anemia
Palpitations or chest pain	Dysrhythmias
	Anxiety, panic disorder
Recent life stressor	Anxiety
Last menstrual period	Pregnancy
Motion sickness	Benign paroxysmal vertigo of childhood
	Migraine
	Vestibular neuritis
Recent upper respiratory infection	
Fever	Otitis media
	Labyrinthitis
Ear trauma, barotrauma	Perilymph fistula
Headache	Migraine
	CNS disease
Head trauma	Temporal bone fracture
	Labyrinth or brainstem concussion
	Cerebellar contusion
	Perilymph fistula
Neurologic deficits	CNS tumor
	Multiple sclerosis
Hearing loss	Cholesteatoma
	Acoustic neuroma
	Temporal bone fracture
	Perilymph fistula
	Labyrinth concussion
	Labyrinthitis
	Ramsay-Hunt syndrome (herpes zoster oticus)
	Ménière disease
Triggered by change in head position	Benign paroxysmal positional vertigo
	Perilymph fistula
	Vestibular neuritis
	Acute labyrinthitis
Loss of consciousness or altered mental status	Seizure
	Dysrhythmia
	Vasovagal syncope
	CNS disease
	Hypoglycemia

CNS, central nervous system.

help in the diagnosis of perilymph fistula are applying pressure to the tragus to occlude the external auditory canal and pneumatic otoscopy; these may induce nystagmus or vertigo and transiently worsen a hearing loss.

### Laboratory Testing and Imaging

With a limited role in the evaluation of dizziness and vertigo, laboratory tests such as complete blood count, metabolic panel, thyroid function tests, electrocardiogram, electroencephalogram, and magnetic resonance imaging should be guided by the history and physical examination. In adolescent girls, a pregnancy test should also be considered. Formal audiometry and electronystagmography may be warranted for the evaluation of vertigo.

## MANAGEMENT OF DIZZINESS AND VERTIGO

For patients who have presyncopal or orthostatic dizziness, reassurance and instructions about adequate hydration, about care when arising suddenly, and about the necessity of putting the head lower than the heart when symptoms occur generally suffice for patient management. For patients in whom dizziness is part of a panic attack or a marker of significant stress, further history should be obtained, including any suicidal ideation, and referral for counseling considered.

Treatment for migrainous vertigo and its related syndromes should be symptomatic and targeted to the treatment of migraines (see Chapter 157, Headache).

Vestibular suppressants such as diazepam, meclizine (for children >12 years), and dimenhydrinate may be used to relieve the symptoms of vertigo and nausea. Antibiotics are required for treating labyrinthitis. Treatment for postinfectious vestibular neuritis is symptomatic and supportive, but evidence suggests that prednisone may be helpful.

### WHEN TO REFER

- Acute ataxia
- A clear history of vertigo, especially with other neurologic signs, or after head trauma or barotrauma
- Suspected perilymph fistula or cholesteatoma
- Suspected seizure
- Complicated migraine

### WHEN TO ADMIT

- Bacterial or suppurative labyrinthitis
- Head trauma with temporal bone fracture
- Space-occupying lesions
- Potential life-threatening cardiac dysrhythmias
- Labile hypertension

## Chapter 141

# DYSMENORRHEA

Linda M. Dinerman, MD, PC

Dysmenorrhea, or painful menstruation, is a syndrome characterized by varying degrees of crampy, lower abdominal pain and other symptoms such as nausea, vomiting, urinary frequency, low back pain, diarrhea, fatigue, thigh pain, nervousness, dizziness, sweating, and headache. The pain typically begins just after menses and lasts for about 1 to 2 days, but it can also begin 1 to 2 days before the onset of menses and can last up to 4 days into menstruation. Cramps may be more severe among teenagers who smoke. At least 40% to 60% of adolescent girls suffer some degree of discomfort during menstruation, with about 15% reporting severe symptoms and 14% reporting that they frequently miss school as a result of menstrual symptoms. Most affected teenage girls have primary dysmenorrhea not associated with pelvic or other pathologic conditions; however, causes of secondary dysmenorrhea always should be considered when the patient is evaluated.

## PRIMARY DYSMENORRHEA

Increased amounts of prostaglandins  $E_2$  and  $F_{2\alpha}$  in the endometrium of women with dysmenorrhea lead to smooth muscle contractions along with other symptoms such as vomiting and diarrhea. This biologic explanation correlates with the clinical observation that women who have anovulatory cycles usually do not have dysmenorrhea. Adolescent girls typically develop dysmenorrhea 1 to 2 years after menarche, correlating with the onset of ovulatory cycles.

The incidence of dysmenorrhea increases with gynecologic age (as does the number of ovulatory cycles), with up to 31% of girls reporting dysmenorrhea in their first year of menses and 78% in their fifth year. The increase in prostaglandin synthesis may be related to changes in serum progesterone levels not seen in anovulatory women. Additional confirmation comes from the dramatic response women experience with use of either prostaglandin synthetase inhibitors or oral contraceptives, which

inhibit ovulation. Increased levels of prostaglandin activity are associated with increased uterine tone and high-amplitude myometrial contractions, both of which result in reduced uterine blood flow and pain.

The assessment of a teenager with dysmenorrhea should include the following:

- Complete menstrual history
- Timing of cramps or pain
- Missed school or other activities
- Ability to participate in social events
- Presence of nausea, vomiting, diarrhea, dizziness, or other symptoms
- Medications used, including doses
- Factors that improve or worsen symptoms
- Family history of dysmenorrhea or endometriosis

In some cases, dysmenorrhea may be the presenting complaint when the true agenda is otherwise. For example: Is the patient reluctant to attend school? Does the patient have a history of physical or sexual abuse? Does the patient have significant psychosocial problems? Is the teen secretly sexually active, and is this a way for her to obtain oral contraceptives for the purpose of contraception?

A careful history usually excludes most pathologic causes of dysmenorrhea. Physicians differ in their opinions regarding what examination is necessary to evaluate a patient with dysmenorrhea. In general, for a non-sexually active teenager who has mild to moderate menstrual cramps relieved by nonsteroidal anti-inflammatory drugs (NSAIDs), only an external genital examination to rule out hymenal abnormalities is indicated. Some physicians would also initiate oral contraceptive pills for a few cycles before performing a pelvic examination if the dysmenorrhea is unresponsive to NSAIDs. For any sexually active teenager or, in the opinion of some experts, for one who is having significant pain that is unresponsive to NSAIDs, a thorough pelvic examination is necessary. In sexually active teenagers, evaluation for sexually transmitted infections and pregnancy should be included. If a pelvic examination is not possible, then a rectoabdominal examination will provide some useful information about the presence of masses or adnexal tenderness. A pelvic ultrasound may be useful in defining uterine and vaginal abnormalities associated with obstruction but is not helpful in the detection of pelvic or abdominal adhesions or endometriosis.

Although treatment of primary dysmenorrhea is likely to include drug therapy, the physician also should take the valuable opportunity to teach the patient about her body. Many teenagers do not understand the physiologic mechanisms of menstruation fully or may have inaccurate beliefs that have been passed on from mother to daughter.

Although teenagers who have very mild discomfort benefit from almost any analgesic, prostaglandin synthetase inhibitors in the form of NSAIDs are the treatment of choice for most young women with dysmenorrhea. Doses, both in terms of amount and timing, vary from patient to patient. Establishing not only prior use of specific medications but also doses is important, given that most patients use them in

subtherapeutic amounts. Some need medication only for part or all of the first day of menstruation; others require medication for up to 4 days or more. Ibuprofen (200–800 mg every 6–8 hours) is highly effective for dysmenorrhea, as is naproxen sodium (550 mg immediately and then 275 mg every 6–8 hours). Mefenamic acid, an NSAID that blocks the effect of prostaglandin at the end-organ level and inhibits its production, can be used in a dose of 500 mg administered immediately, followed by 250 mg every 6 hours. Celecoxib, a cyclooxygenase inhibitor, in a dose of 200 mg every 12 hours, has been shown to be effective; however, intestinal bleeding and cardiovascular events have limited its use. In 1 study, 57% of adolescents used medications less often than the maximal daily frequency; thus, advising patients of the range of correct doses is important. These medications are most effective if started at the first sign of menstrual bleeding; women who experience significant nausea with menses may benefit from starting treatment at the earliest symptom of menses, even before bleeding occurs. If the adolescent fails to respond to 1 type of NSAID (eg, ibuprofen), then another (eg, naproxen sodium) should be tried because variability is noted in response to different NSAIDs. Between 70% and 80% of girls will respond to one NSAID or another. The patient should be reevaluated after 2 to 3 menstrual cycles to determine effectiveness of the treatment.

Some patients (perhaps as many as 20% to 30%) will not respond to these measures. In these young women, a trial of oral contraceptive pills (OCPs) used in the same way as for contraception usually provides relief. OCPs work by suppressing ovulation and decreasing endometrial prostaglandin production. Patients should be told that 2 to 3 cycles may elapse before contraceptives exert their maximal effect. If the patient is sexually active, then oral contraceptives are continued on a routine basis; for the non-sexually active teenager, therapy can be reassessed at 6- to 12-month intervals.

Low dose OCPs significantly decrease the symptoms of dysmenorrhea in adult women and adolescents. After 3 cycles, adult patients using OCPs with 20 mcg of ethinyl estradiol and 150 mcg of desogestrel and adolescent patients using OCPs with 20 mcg of ethinyl estradiol and 100 mcg of levonorgestrel experienced significant relief of dysmenorrhea compared with those using placebo.

In a study of adolescent girls using the patch (Ortho Evra) for contraception, dysmenorrhea decreased in 39%, increased in 11%, and resulted in no change in 50%. Depot-medroxyprogesterone acetate (Depo-Provera, DMPA) is also used to prevent ovulation and menstrual flow when OCPs are not tolerated or estrogen is contraindicated. An extended oral contraceptive regimen in which OCPs are taken for up to 12 consecutive weeks followed by 1 hormone-free week is another treatment approach. Continuous OCPs have also been well accepted and shown to be effective in eliminating menses, thereby reducing dysmenorrhea. DMPA and extended oral contraceptive regimens decrease

dysmenorrhea, and they decrease the frequency of menses.

The efficacy of other treatments is still unproved. Some experts believe that heat, pelvic exercise, general exercise, biofeedback, relaxation therapy, massage, vitamin E, or various herbal remedies are effective; other authorities remain skeptical of these alternatives. Magnesium has been shown to be beneficial in some studies. To the extent that smoking exacerbates dysmenorrhea, it provides yet another reason for physicians to urge their patients to stop smoking. The adolescent with dysmenorrhea should be encouraged to exercise, eat a well-balanced diet, decrease stress, and decrease caffeine consumption.

Women who fail to respond to any of these measures should be referred to an adolescent medicine specialist or gynecologist for evaluation; they probably have secondary rather than primary dysmenorrhea.

## SECONDARY DYSMENORRHEA

Causes of secondary dysmenorrhea, such as pelvic inflammatory disease (PID), endometriosis, and conditions arising in a variety of other organ systems, can usually be excluded by a careful history and physical examination. Underlying pathologic conditions should be anticipated in a young woman whose pain begins after 20 years of age, who has a history of surgery related to the genitourinary or gastrointestinal tract, or who has pain that is dull and constant rather than crampy.

Endometriosis is the presence of functional endometrial glands and stroma outside the normal anatomic location in the uterus. Patients who have endometriosis will have failed therapy with NSAIDs and oral contraceptives, and their pain may be acyclic rather than cyclic. Menstrual bleeding may be irregular, gastrointestinal symptoms may be present, and a family history of endometriosis can often be elicited. Endometriosis also may be associated with dyspareunia, tenesmus, and rectal pain. Some studies of teenagers with chronic pelvic pain show 25% to 38% of those undergoing laparoscopy have endometriosis. In yet other studies, 52% to 73% of teenagers with chronic pelvic pain have evidence of endometrial implants. PID can cause dysmenorrhea acutely, and women often develop chronic pelvic pain as a consequence of PID. Even with assurances of confidentiality, some young women may still not admit to sexual activity. Hence, physicians must maintain a high index of probability if other historical and physical examination findings suggest PID. Teenagers who have a history of genital tract surgery, including abortion, may have outflow tract obstruction. A variety of müllerian anomalies with incomplete obstruction of the outflow tract also produce dysmenorrhea. Depending on the type of obstruction, a pelvic mass may be palpable. Endometrial polyps or fibroids are rare in women younger than 20 years but should be anticipated if the menstrual bleeding is heavy, prolonged, or associated with the passage of clots. Whether these entities alone cause dysmenorrhea is unclear.

A pelvic examination that reveals cervical motion tenderness, or adnexal tenderness, or masses strongly suggests PID. If the cervical os is stenotic or the

cervix or uterus feels atretic or abnormally shaped, then outflow obstruction is possible (eg, a uterus with a blind horn). Among adult women, physical findings such as small fixed nodules in the rectovaginal septum or cul de sac or fixation of the uterus indicated by the sensation of pain on stretching of the uterosacral ligaments suggest endometriosis. However, most adolescents generally have normal examinations; hence, endometriosis can be extremely difficult to detect on clinical grounds alone. If a secondary cause of dysmenorrhea is thought to be present, then consultation with an adolescent medicine specialist or gynecologist is warranted. Ultrasound examination of the uterus will rule out uterine anomalies but cannot exclude endometriosis. Confirmation of endometriosis requires laparoscopy. Because the lesions of endometriosis in adolescents may differ from the typical lesions seen in adults, a gynecologist who is experienced in evaluating adolescents should perform this procedure. Endometriosis may be difficult to manage, and women who have this condition are at increased risk for infertility.

PID should be treated according to standard antibiotic regimens. Follow-up is critical because young women, once infected, are at risk for further episodes of PID as well as for chronic pelvic pain, ectopic pregnancy, and infertility.

### WHEN TO REFER

- For dysmenorrhea, referral might be appropriate if
- Physician feels uncomfortable prescribing OCPs for the treatment of primary dysmenorrhea
- Patient fails to respond to NSAIDs and OCPs
- Clinical presentation or course suggests that the patient has secondary rather than primary dysmenorrhea
- Patient is sexually active and the physician feels uncomfortable performing a pelvic examination

### WHEN TO ADMIT

If the cause of the dysmenorrhea is determined to be PID, some physicians would recommend hospitalization of all adolescents for treatment. Others recommend hospitalization under certain but not all circumstances.

## TOOLS FOR PRACTICE

### Engaging Patient and Family

- *Center for Young Women's Health* (Web site), ([www.youngwomenshealth.org](http://www.youngwomenshealth.org))

## Chapter 142 DYSPHAGIA

Mohammad F. El-Baba, MD

Feeding and swallowing disorders are common complaints in children. Dysphagia is defined as difficulty swallowing, which derives from the Greek root, *dys*, meaning “difficulty,” and *phagia*, meaning “to eat.” It is not synonymous with the term *odynophagia*, which refers to painful swallowing.

### NORMAL DEVELOPMENT OF SWALLOWING

A sucking reflex, present as early as 18 weeks’ gestation, is initially disorganized but becomes more organized and efficient for feeding by 34 to 36 weeks’ gestation. For the term newborn the suck is mature and efficient for liquid feedings. During early infancy, the infant develops a more rapid suck rate and higher suck pressure. Tongue movements are differentiated and become more coordinated, preparing the infant for pureed food by 5 to 6 months of age. After this stage, sensory experience with food increases, and oral motor skills expand to handle more textured food. The gag reflex decreases to allow swallowing of an increasing amount of food with more texture. By age 2 years, chewing and tongue movements become more proficient.

### NORMAL PHASES OF SWALLOWING

Swallowing is divided into 3 phases: oral, pharyngeal, and esophageal. These phases allow the food and liquid to move from mouth to stomach efficiently and safely. In the oral phase, the food is mixed with saliva and chewed if needed. A single bolus of food is collected between the roof of the mouth and tongue. The bolus is propelled to the posterior of the tongue and then to the pharynx. In infants and young children, the suckling swallow allows the liquid to fall from the mouth into the pharynx.

The pharyngeal phase is the actual reflexive swallow stimulated by the presence of food on the posterior tongue. During this phase the soft palate rises to keep the food from the nasal passage. The larynx moves up and forward, closing the glottis. The vocal cords come together, the epiglottis closes over the airway, and respirations cease. Food is propelled further by contraction of the pharyngeal muscles and relaxation of the upper esophageal sphincter.

During the esophageal phase, esophageal peristalsis moves the food down the esophagus into the stomach through the relaxed lower esophageal sphincter. The lower esophageal sphincter then returns to the closed tonic state to prevent regurgitation of gastric contents.

### CAUSES OF DYSPHAGIA

Any anatomic or functional disorder in the well-coordinated act of swallowing can result in dysphagia,

which can be for liquids, solids, or both. In general, mechanical or obstructive factors result in dysphagia for solids. Dysphagia for liquids is more pronounced in patients with neurologic disorders. The causes of dysphagia in children are widespread and include congenital, inflammatory, infectious, systemic, neoplastic, and traumatic reasons (Box 142-1).

Infants born before term or with a birth weight below the tenth percentile for gestational age are at increased risk for developing dysphagia and feeding difficulties. Improved survival of infants born prematurely has contributed to the increased incidence of dysphagia in children.

Central nervous system impairment and developmental delay are common causes of dysphagia in infants and children. Almost all children with severe cerebral palsy are reported to suffer from some degree of dysphagia, and about 70% of children with severe traumatic brain injury present with dysphagia during the acute phase of care. Children with gastroesophageal reflux disease often experience some feeding problems and food refusal. Reflux can lead to nausea, vomiting, and esophagitis, all of which may cause feeding to be perceived as an aversive experience. Eosinophilic esophagitis has become a recognized entity that causes dysphagia in adults and children, and it should be considered in the differential diagnosis of children with unexplained oral aversion, feeding difficulties, and poor weight gain.

Prolonged tube feeding in infancy or childhood can lead to long-term feeding difficulties. Several factors are implicated in such difficulties and include age at which oral feeding commences, underlying medical conditions, exposure to taste and textures during sensitive periods, aversive experiences, and different methods of delivering tube feeds.

Infants and young children occasionally exhibit transient feeding difficulties such as selective eating, exceedingly slow eating, and tantrums. Some children without apparent risk factors show deviating feeding behaviors such as food refusal, aversion to feeding, low food intake, excessive gagging, and vomiting even before food is presented. Nonorganic feeding disorders are usually transient, but in 3% to 10% become persistent and carry the risk of inadequate growth. Early intervention and a multidisciplinary approach are crucial in the management of this group of children.

### CLINICAL MANIFESTATION

Feeding disorders are commonly seen in early childhood. Minor feeding problems are reported in 25% to 35% of healthy young children, with major feeding disorders observed in 40% to 70% of infants born prematurely or children with chronic medical problems. Affected infants or children commonly exhibit feeding difficulties, food refusal, failure to thrive, or sensation of food stuck in the throat or chest. These children may also have drooling, difficulty initiating swallowing, change in dietary habits, aversions to certain food textures, and unexplained weight loss.

**BOX 142-1 Causes of Dysphagia in Children**

- Prematurity
- Congenital abnormalities
  - Congenital anomalies of the nasal and oral cavity
    - Cleft lip or palate
    - Choanal atresia or stenosis
    - Craniofacial anomalies (Crouzon syndrome, Apert syndrome, Möbius sequence, Pierre Robin sequence, Treacher Collins syndrome)
    - Congenital nasal masses (dermoids, encephaloceles)
  - Congenital anomalies of the larynx, trachea, and esophagus
    - Laryngomalacia
    - Laryngeal clefts
    - Laryngeal stenosis and webs
    - Vocal cord paralysis
    - Tracheoesophageal fistula
    - Esophageal atresia
    - Esophageal duplication
- Vascular rings
  - Double aortic arch
  - Right aortic arch with left ligamentum from a descending aorta
  - Innominate artery tracheal compression
- Infectious causes
  - Acute pharyngitis or tonsillitis
  - Peritonsillar and retropharyngeal abscesses
  - Epiglottitis
  - Esophagitis (cytomegalovirus, herpesvirus, *Candida albicans*)
- Inflammatory causes
  - Esophagitis secondary to gastroesophageal reflux disease
  - Eosinophilic esophagitis
- Neurologic or neuromuscular disorders
  - Hypoxic-ischemic encephalopathy
  - Head trauma
  - Cerebral palsy
  - Congenital malformations (Arnold-Chiari malformation, absent corpus callosum)
  - Degenerative diseases of white and gray matter
  - Brainstem tumors
  - Syringomyelia
  - Infantile spinal muscular atrophy (Werdnig-Hoffmann disease)
  - Diseases of neuromuscular junction
    - Myasthenia gravis
    - Guillain-Barré syndrome
    - Botulism
- Muscular
  - Congenital myopathies
  - Mitochondrial diseases
  - Glycogen storage diseases
  - Congenital muscular dystrophy and myotonic dystrophy
- Traumatic
  - External trauma
  - Intubation injury
- Neoplastic
  - Hemangioma
  - Lymphangioma
- Miscellaneous
  - Foreign-body aspiration
  - Caustic ingestion
  - Motor dysfunction of esophagus (achalasia)
  - Epidermolysis bullosa

Some children may experience change in voice, recurrent coughing, or noisy breathing during feeding. Oropharyngeal dysphagia should be considered in young children with recurrent aspiration or unexplained respiratory symptoms. Respiratory symptoms that result from dysphagia vary and may be associated with coughing, chronic congestion, recurrent choking, acute life-threatening events, recurrent pneumonias, and chronic lung disease. The different symptoms of dysphagia in infants and children are summarized in Box 142-2.

**EVALUATION****History and Physical Examination**

A complete history and thorough physical examination of the child with dysphagia usually leads to the diagnosis and guides the selection of further diagnostic tests. Emphasis should be placed on birth history, neurodevelopmental history, and medical comorbidities.

Detailed feeding history should include the type of current diet, texture, route of administration, meal duration, and specific food aversion or aversions. General examination should document any orofacial malformation. The combination of micrognathia and glossoptosis seen in Pierre Robin sequence may cause feeding difficulty in an infant. Cleft lip and palate, including submucous cleft, are important causes of dysphagia. Newborns with choanal stenosis may experience difficulty feeding because of the obligate nasal breathing in the first few months of life. Neurologic examination should include assessment of muscle tone and strength and evaluation of cranial nerve function.

A clinical feeding evaluation should be performed by an experienced occupational therapist or speech pathologist. This clinical evaluation includes assessment of posture, positioning, oral structure and function, patient motivation, and interaction between the infant and feeder. A variety of foods, different

**BOX 142-2 Symptoms of Dysphagia in Infants and Children****ORAL PHASE**

- Failure to initiate or maintain sucking
- Prolonged feeding time
- Drooling

**ORAL HYPERSENSITIVITY**

- Exaggerated gag reflex
- Difficulty making the transition to textured foods
- Sensitivity to touch in and around mouth

**ORAL HYPOSENSITIVITY**

- Retaining food in the mouth
- Increased drooling

**PHARYNGEAL PHASE**

- Coughing
- Choking
- Noisy breathing during feeding
- Nasopharyngeal reflux

**ESOPHAGEAL PHASE**

- Spitting up or vomiting
- Irritability or arching during feeding
- Preference for liquid food
- Sensation of food stuck in the throat

positions, and adaptive utensils may be used during the examination. Specific symptoms observed during feeding can help identify the underlying disorder. Gagging, coughing, or emesis is usually present in infants with a structural or neurologic disorder. Repeated swallowing after feeding, fussiness, crying, or regurgitation are usually noted in infants with gastroesophageal reflux disease and require further investigation.

**Laboratory Evaluation**

A complete blood count can be useful as a screening test for infectious or inflammatory conditions. Serum protein and albumen are useful for nutritional assessment. Chromosomal karyotyping, metabolic analysis, or specific DNA tests may be required for a specific diagnosis as directed by physical and neurologic examination. Electromyography, nerve conduction studies, and muscle biopsy may be needed in infants with suspected neuromuscular disorders.

**Imaging Studies**

Chest radiography is indicated in patients with suspected pneumonia or chronic lung disease. Persistent pulmonary infiltrates on chest radiograph may be better elucidated by high-resolution chest computed tomography (HRCT). Computed tomography or magnetic resonance imaging of the brain may be especially

helpful in patients with suspected central nervous system injury or structural abnormalities.

**Diagnostic Studies*****Upper Gastrointestinal Barium Study***

Barium radiography plays a role in evaluating esophageal dysphagia. It is valuable in assessing anatomic or structural abnormalities, such as strictures, fistulas, masses, or intestinal rotational anomalies. Barium studies are usually more sensitive than endoscopy in the evaluation of patients suspected to have achalasia or vascular ring. In most cases, vascular rings appear as a persistent indentation of the esophagus.

***Videofluorographic Swallowing Study***

The videofluorographic swallowing study (VFSS), also known as the modified barium study, is considered the gold standard for assessment of the oral and pharyngeal stages of swallowing and allows the physician to determine the risk of aspiration. Conducted jointly by a radiologist and a dysphagia-trained speech pathologist or occupational therapist, the VFSS provides evidence of all categories of oropharyngeal swallowing dysfunction, which include inability or excessive delay in initiation of pharyngeal swallowing, aspiration of food, nasopharyngeal regurgitation, and residue of food within the pharyngeal cavity after swallowing.

During this study the child will drink or eat foods mixed with barium while radiographic images are observed and recorded. Patients' difficulties with different food textures can be identified and compatible diets planned. The definitive finding of aspiration will permit the physician to make suggestions to avoid the offending consistency, usually thin liquids. Furthermore, the study allows for testing of the efficacy of compensatory dietary modifications, postures, and swallowing maneuvers so that the observed dysfunction can be corrected. Its disadvantages are those of exposure to ionizing radiation, hence a time limit on the study duration and a need for patient cooperation. Dose limiting techniques, such as pulsed fluoroscopy and tight coning, will be effective in eliminating unnecessary radiation.

***Fiberoptic Endoscopic Evaluation of Swallowing***

In fiberoptic endoscopic evaluation of swallowing (FEES) a fiberoptic endoscope is introduced into the nose and advanced into the laryngopharyngeal area, permitting observation of the pharyngeal phase of swallowing. A swallowing assessment is performed with liquids and a variety of textures, if developmentally appropriate. Typically, dye is added to the food to provide better visualization and to determine residual pooling of food versus saliva. The feeding parameters evaluated in this study are laryngeal penetration and aspiration. FEES, combined with laryngopharyngeal sensory testing, has shown that patients with a higher laryngopharyngeal sensory threshold are more likely to experience laryngeal

penetration and aspiration during a feeding assessment. The ability to initiate airway closure with stimulation demonstrates airway protection. FEES and sensory testing may be particularly valuable for the evaluation of swallowing safety in children who refuse to ingest adequate amounts of barium to perform VFSS.

### **Esophagogastroduodenoscopy**

Endoscopy is suggested for most patients with dysphagia of esophageal origin to establish or confirm a diagnosis, to seek evidence of esophagitis, and, when appropriate, to implement therapy. It is particularly useful in evaluating patients suspected of having strictures, webs, mucosal inflammatory lesions, or specific infections. Endoscopic and histologic features are required for the diagnosis of eosinophilic esophagitis. A normal appearance of the esophagus during endoscopy does not exclude histopathological esophagitis; subtle mucosal changes such as erythema and pallor may be observed in the absence of esophagitis. During endoscopy, esophageal biopsy should be performed to detect microscopic esophagitis and to exclude causes of esophagitis other than gastroesophageal reflux.

### **Esophageal Manometry**

Esophageal manometry, the standard test for disorders of esophageal motility, is especially useful in establishing a diagnosis of achalasia and for detecting esophageal motor abnormalities associated with autoimmune diseases.

### **Esophageal pH Probe Study**

Esophageal pH monitoring, a valid and reliable measure of acid reflux, is useful to establish the presence of abnormal acid reflux, to determine whether a temporal association exists between acid reflux and frequently occurring symptoms, and to assess the adequacy of therapy in patients who do not respond to treatment with acid suppression. Most centers are currently replacing pH monitoring with combined multiple intraluminal impedance (MII) and pH monitoring. This test detects acid and nonacid reflux episodes. It is superior to pH monitoring alone for evaluation of the temporal relation between symptoms and GER.

### **Scintigraphy**

Scintigraphy is useful in the evaluation of gastric emptying and can also demonstrate episodes of aspiration detected during a 1-hour study or on images obtained up to 24 hours after the test feeding is administered. The role of scintigraphy in diagnosing gastroesophageal reflux disease in infants and children is unclear.

## **MANAGEMENT**

Management of children with dysphagia often involves a multidisciplinary approach, the aims of which are to identify and characterize dysphagia and identify the underlying cause whenever possible. Special emphasis should be placed on detection of treatable

conditions, which include surgically or endoscopically treatable structural abnormalities, inflammatory conditions (eg, reflux esophagitis, eosinophilic esophagitis), specific infections, and underlying systemic conditions.

The goals of managing dysphagia are to reduce aspiration, improve the ability to eat and swallow, and optimize nutritional status. Feeding therapy for infants and children may include the strategies described below.

### **Normalization of Posture and Tone**

Head and trunk control are crucial to the development of oral motor skills. Children with neurologic abnormalities frequently have poor head control and poor trunk stability. Occupational and physical therapy can be used to improve head control, neck and trunk tone, and posture as a basis for improved oral motor function.

### **Adaptation of Food and Feeding Equipment**

Food and feeding equipment may be adapted by changing the attributes of food and liquids, such as bolus volume, consistency, temperature, and taste. Adjustments in feeding schedule may be beneficial for children receiving continuous tube feeds with supplemental food orally. The feeds can be changed gradually to bolus feeds to stimulate the child's appetite. The rate of feeding should be paced to allow sufficient time to swallow before giving another bite. In addition, the bottle or utensils may be changed according to the child's needs.

### **Oral Motor Therapy**

Oral motor therapy is focused on improving the oral phase of feeding and may include stimulation with stroking, stretching, brushing, icing, tapping, and vibrating areas of the face and mouth.

### **Nutritional Support**

Management of dysphagia must focus on meeting the child's nutritional needs for adequate growth. When a patient is unable to achieve adequate nutrition and hydration by mouth, supplemental feedings through a nasogastric tube or a percutaneous endoscopic gastrostomy may be necessary. The presence of a feeding tube is not a contraindication for therapy. Many children with feeding disorders have neurologic or anatomic abnormalities that cannot be corrected, making oral feeding difficult or unsafe.

## **MANAGEMENT OF ASSOCIATED DISORDERS**

Associated disorders, such as gastroesophageal reflux disease, eosinophilic esophagitis, and chronic lung disease, may also need to be specifically managed. Application of synchronized neuromuscular electrical stimulation to cervical swallowing muscles (VitaStim therapy) has been shown to improve oral intake and help restore normal swallowing mechanism in adults, but empirical data are lacking to support its use in children.

**WHEN TO REFER**

A referral to a pediatric dysphagia center, if available, provides the most complete method to establish a diagnosis and render a management plan. Members of the team vary from center to center and usually include a gastroenterologist, otolaryngologist, pulmonologist, physical medicine and rehabilitation specialist, surgeon, occupational therapist, and pediatric dietitian. Referral is warranted

- When symptoms are persistent
- When the cause of dysphagia is unclear
- On evidence of aspiration

**WHEN TO ADMIT**

- Severe feeding difficulties
- Malnutrition
- Failure to thrive
- Dehydration
- Aspiration

## Chapter 143

### DYSPNEA

Jay H. Mayefsky, MD, MPH

Dyspnea is the uncomfortable feeling of not being able to satisfy *air hunger*. Patients may complain of not being able to catch their breath or of a suffocating feeling. As with any subjective complaint, the diagnosis of dyspnea and its cause in an infant or young child can be problematic. Therefore, to evaluate fully a child in respiratory distress, the pediatrician must be familiar with the pathophysiologic features, signs, and common causes of dyspnea. With the aid of the medical history, physical examination, and appropriate laboratory tests, the condition can be diagnosed and therapy initiated.

**PATHOPHYSIOLOGIC FEATURES**

Dyspnea is seen most commonly with exercise because of the increased work of breathing necessary to keep up with the body's increased metabolic demands. The sensation is probably transmitted from stretch receptors in the chest wall muscles to the central nervous system (CNS). Chemoreceptors play a role, sensing changes in arterial pH, oxygen, and carbon dioxide concentrations, as well as chest wall proprioceptors, lung stretch receptors, and mechanoreceptors in the heart, skeletal muscles, and upper airway. The transmission is processed in the CNS, causing the individual to experience the sensation of dyspnea. With exercise, the person who has dyspnea is aware of an increased ventilatory effort. Under these circumstances, the dyspnea is relieved after the exercise ceases and the pH and oxygen and carbon dioxide levels return to normal. Dyspnea also occurs when ventilation or gas exchange is compromised.

To satisfy their oxygen needs, children who have dyspnea must increase their minute ventilation ( $\dot{V}_E$ ), working harder to do so. In normal breathing, respiratory muscles work only during inspiration, and the diaphragm does most of the work. The work of inspiration is the sum of the work necessary to overcome the elastic forces of the lung, the tissue viscosity of the lung and chest wall, and airway resistance. When any of these factors is increased (eg, elastic force and tissue viscosity in restrictive pulmonary disease, resistance in obstructive airway disease), the work of inspiration must increase to maintain adequate  $\dot{V}_E$ . The accessory muscles of inspiration (the sternocleidomastoid, anterior serratus, and external intercostal muscles) are recruited to accomplish this task. Contraction of these muscles causes forceful expansion of the thorax, resulting in an unusually large negative intrathoracic pressure. This negative pressure draws in the soft tissues of the chest wall and creates 1 of the classic signs of dyspnea, retractions, which may be seen in the suprasternal, infrasternal, intercostal, subcostal, and supraclavicular areas. An alternative way to maintain an adequate  $\dot{V}_E$  is to increase the rate of breathing; hence the second classic sign of dyspnea, tachypnea. Nasal flaring and grunting are other signs during respiration.

Little energy is expended during normal expiration. Relaxation of the diaphragm, elastic recoil of the lungs and chest wall, and compression of the lungs by the intra-abdominal organs force air from the lungs. In obstructive airway disease the force generated by these processes may not be great enough to effect adequate expiration. With tachypnea the elastic recoil may not be fast enough to allow adequate exhalation between breaths. In either instance the accessory muscles of expiration are used. The abdominal recti muscles contract and force the abdominal contents against the diaphragm to compress the lungs, and the internal intercostal muscles contract to pull the ribs downward and create a positive intrathoracic pressure to force the air from the lungs. The contractions of these muscles

provide the most important expiratory sign of dyspnea.

Although dyspnea is a respiratory symptom, it may be caused by primary disorders in other body systems. Cardiac, hematologic, metabolic, circulatory, and psychogenic causes must be considered in the differential diagnosis of dyspnea. The child's age is also important, because the frequency of some disorders may vary with age.

### History

The history begins with a complete description of the dyspnea. The patient or parent should be asked whether the onset was sudden (eg, inhaled foreign body, lung collapse) or evolved over several hours (eg, asthma, diabetic ketoacidosis). The patient should also be asked about the duration of the illness, the frequency of attacks of dyspnea, and whether a trigger or event is apparent that is temporally related to the onset of dyspnea. An attempt should be made to quantify the severity of the dyspnea. This task may be accomplished by asking to what degree daily activities are restricted by shortness of breath. However, given that dyspnea is a subjective sensation, its perceived severity can be affected by the patient's anxiety level, previous experiences, perceived control over the symptom, perceived consequences of the symptom, and available coping resources. The chronic use of medications such as inhaled corticosteroids and  $\beta_2$ -agonists has also been shown to have an effect on the patient's perception of dyspnea. Therefore, whenever possible, objective measures as discussed here should be obtained.

An inquiry should be made as to whether the dyspnea is affected by the patient's position. With unilateral lung disease, dyspnea may get worse when the patient lies with the affected lung down. Dyspnea that worsens with recumbency is often caused by left-ventricular failure, obstructive airway disease, or muscle weakness. Dyspnea in the upright position relieved by lying down usually is caused by intracardiac, vascular, or parenchymal lung shunts.

The patient should also be asked about associated symptoms such as cough, wheezing, sputum production, and pleuritic pain. In addition, a history of other known illnesses, allergies, illnesses in the family, medication, and environmental exposure must be obtained.

### Clinical Evaluation

A thorough physical examination is always indicated, with special attention paid to the aforementioned systems. The most useful laboratory tests are the complete blood count and peripheral blood smear, arterial blood gas measurement, and radiographic studies of the airways and lungs. Measurement of arterial oxygen saturation by pulse oximetry is invaluable for its capacity to assess oxygenation status quickly and non-invasively. Pulmonary function tests are helpful but may not be immediately available for evaluation of an acutely ill patient.

## ETIOLOGY AND CLINICAL PRESENTATION

### Pulmonary Disease

Pulmonary disease that causes dyspnea can be classified as obstructive, restrictive, or vascular.

#### Obstructive Pulmonary Disease

Obstructive disease is characterized by narrowing of airways that can be caused by intraluminal objects (mucus, foreign bodies, or tumor), intramural factors (smooth-muscle contraction, edema, or bronchomalacia), or extramural compression (tumor or lymph nodes). The narrowing increases both airway resistance and turbulent flow in the airways. If a fixed obstruction is present, then affected areas of the lungs will become atelectatic. With a ball valve-type obstruction (ie, air can get into the lungs but not out), air is trapped, and affected areas become hyperinflated. In either case, an imbalance occurs between pulmonary ventilation and perfusion, and oxygen exchange is adversely affected. All of these processes force the patient to work harder to maintain adequate ventilation; dyspnea ensues.

During normal respiration, inspiration and expiration are of equal length. With a fixed degree of obstruction, both processes are equally prolonged. If the obstruction varies and is extrathoracic (ie, above the vocal cords), then inspiration is affected more because the negative intra-airway pressure during inspiration tends to collapse the extrathoracic airway. The characteristic sign of such an obstruction is inspiratory stridor (see Chapter 197, Stridor).

If the obstruction varies and affects the intrathoracic airways, then expiration is prolonged because the positive intrathoracic pressure tends to collapse these airways during expiration. If larger airways are involved, then rhonchi are present. Airflow across an obstruction in smaller airways generates wheezing.

A paradoxical pulse and cyanosis are sensitive, but nonspecific, signs of severe obstruction. Patients who have chronic obstructive disease may be barrel chested and have signs of chronic hypoxia such as clubbing. Children who have a systemic disease, such as cystic fibrosis, will also show the extrapulmonary manifestations of this disease. The common causes of obstructive airway disease in childhood are shown in Box 143-1. Obstruction in the nose or nasopharynx should not be overlooked, especially in infants who are obligatory nasal breathers.

Blood gas values may be normal with mild obstructive disease. As the disease progresses, hypoxemia is the first sign of abnormality. Hypocapnia, initially seen as a reflection of increased VE, is replaced by hypercapnia as the maldistribution of ventilation and perfusion increases. The patient then tires, and respiratory failure occurs.

The chest radiograph may reveal whether the cause of the obstruction is inside or outside the airway. In many instances, hyperinflation with an increased anteroposterior chest diameter and flattened diaphragm are seen. Atelectasis may appear with a fixed

### BOX 143-1 Causes of Obstructive Pulmonary Disease

#### NEWBORNS

- Choanal atresia or stenosis
- Dermoid cyst
- Encephalocele
- Nasolacrimal duct cyst
- Hemangioma
- Vocal cord paralysis
- Pierre Robin sequence
- Ankyloglossia (tongue tie)
- Pertussis
- Tracheal stenosis (postintubation)

#### INFANTS

- Foreign body
- Vascular ring
- Tracheal web
- Bronchiolitis
- Asthma
- Cystic fibrosis
- Bronchomalacia
- Pyogenic thyroid
- Accessory thyroid

#### CHILDREN AND ADOLESCENTS

- Foreign body (airway or esophagus)
- Asthma

- Adenopathy
  - Lymphoma
  - Systemic lupus erythematosus
  - Tuberculosis
  - Sarcoidosis
- Croup
- Epiglottitis
- Retropharyngeal abscess
- Enlarged tonsils or adenoids
- Cystic fibrosis
- Anaphylaxis
- Laryngeal tumor
- Vocal cord tumor
- Tracheal tumors
- Mediastinal tumors
- Vocal cord polyp
- Laryngeal trauma
- Supraglottitis
- Diphtheria
- Bacterial tracheitis
- Ingestion of caustic substance
- Crack cocaine
- Trauma
- Environmental or occupational inhaled toxin exposure

obstruction. Fluoroscopic examination or inspiratory and expiratory radiographs may be useful in localizing a ball valve-type obstruction. However, an important point to remember is that many foreign bodies are radiolucent and will not be seen on radiographic examination. If a radiolucent foreign body is suspected, then laryngoscopy, bronchoscopy, or even esophagoscopy may be required.

#### Restrictive Pulmonary Disease

The cardinal features of restrictive pulmonary disease are a reduction in lung volume and pulmonary compliance secondary to pathologic changes in the lung parenchyma or the pleura, deformities of the chest wall, or neuromuscular disease. Decreased volume necessitates an increase in respiratory rate to maintain a normal  $\dot{V}_E$ . The work of breathing must be increased to overcome the reduced compliance. Because breathing rapidly with small tidal volumes is more energy efficient than breathing slowly and attempting to

expand the chest against great restrictive forces, children who have restrictive diseases characteristically have rapid, shallow respirations. The common pediatric causes of restrictive pulmonary disease are listed in Box 143-2.

Observation of the child often reveals skeletal and neuromuscular causes. Pleural and parenchymal diseases are detected best by palpation, percussion, and auscultation of the chest. Tactile fremitus can demonstrate pulmonary consolidation or pleural effusion. Careful percussion reveals effusions, consolidation, and abnormal diaphragmatic excursion. Auscultation can reveal rales characteristic of alveolar disease and changes in whispered pectoriloquy and egophony.

The complete blood count may be helpful in diagnosing an infectious cause. Arterial blood gases have a characteristic pattern of hypoxemia and hypocapnia. The chest radiograph is useful because it can demonstrate decreased lung volume, pleural thickening and effusions, increased interstitial markings, parenchymal consolidation, skeletal deformities, and abnormal movement of the diaphragm.

#### Vascular Pulmonary Disease

Vascular lung disease is characterized by a decrease in the size of the pulmonary vascular bed. In the neonate, this disease often results from persistent pulmonary hypertension of the newborn. Microthrombi have also been reported in the lungs of infants who are in severe respiratory distress. In older children, the most common cause of vascular pulmonary disease is intimal hyperplasia after persistent left-to-right shunting and resultant pulmonary hypertension. The size of the pulmonary vascular bed can also be reduced by obstruction caused by thromboembolic disease, obliteration (eg, vasculitis), or destruction, as in emphysema. The reduced blood flow through the lungs results in arterial hypoxemia and hypercapnia, which, in turn, lead to the symptoms and signs of dyspnea.

In addition to the common signs of dyspnea, the child who has vascular lung disease may have signs of pulmonary edema and pleural effusion. Systemic signs of right-sided heart failure caused by pulmonary hypertension or left-sided heart failure that was the cause of the pulmonary hypertension may be present. The cardiac findings observed with pulmonary hypertension are an accentuated  $P_2$ , paradoxical splitting of second heart sound, a third heart sound, a pulmonary ejection click, and a right-ventricular heave.

An electrocardiogram is helpful in the diagnosis of right-ventricular hypertrophy. A chest radiograph may reveal increased right ventricular size, enlargement of the pulmonary artery silhouette, decreased pulmonary blood flow in advanced disease, or increased flow early in the course of disease, with a left-to-right shunt.

#### Exercise-Induced Dyspnea

As described earlier, dyspnea is a normal sensation felt during exercise, especially for children with a sedentary lifestyle and poor cardiovascular conditioning. However, if the dyspnea is severe, occurs after only

- Pulmonary infarction

minimal exertion, or is troublesome to the patient, then investigations into the cause of exercise-induced dyspnea (EID) are warranted.

Asthma is the most common cause of pathologic EID. However, when other signs and symptoms of asthma are absent, or when pretreatment with beta-agonistic medications does not prevent EID, then other causes must be considered. These causes include vocal cord dysfunction, exercise-induced laryngomalacia, exercise-induced hyperventilation, restrictive airway disease caused by skeletal abnormalities such as scoliosis and pectus deformities, and cardiac arrhythmias that occur only during exercise.

**Cardiac Disease**

Dyspnea occurs with cardiac disease when insufficient blood is pumped to the lungs as a result of congenital structural anomalies in the heart, pump failure (myocarditis or cardiomyopathy), restrictive pericarditis, arrhythmia, or, as already described, secondary pulmonary hypertension. Heart disease must be considered in all dyspneic newborns and older children who have a history of congenital heart disease. In the neonate, pulmonary disease can often be differentiated from cyanotic heart disease through a hyperoxia test. The nature of the cardiac defect can be delineated with the help of a thorough cardiac examination, an electrocardiogram, a chest radiograph, and an echocardiogram.

A trivial respiratory infection in a healthy child may cause severe respiratory insufficiency in a child who has cardiopulmonary disease. Indeed, the mortality of infants who have respiratory syncytial viral pneumonia and congenital heart disease has been shown to exceed significantly the mortality of children who have normal hearts.

### Hematologic Disease

If the oxygen-carrying capacity of the blood is reduced sufficiently, then tissue hypoxia ensues. The resultant drop in arterial pH signals the CNS and stimulates the onset of dyspnea. Severe anemia, whether chronic or acute, congenital or acquired, can cause dyspnea. The oxygen-carrying capacity can also be lowered when the hemoglobin's ability to bind oxygen is reduced, seen most commonly with carbon monoxide poisoning but also with cyanide poisoning and methemoglobinemia. In any of these cases the child will not be cyanotic. The blue color of cyanosis is caused by at least a 5-g/dL reduction of oxygenated hemoglobin in the blood. Such a concentration of reduced hemoglobin is not found in anemia uncomplicated by other diseases or in the other conditions cited. Conversely, an infant with polycythemia whose blood is hyperviscous may have dyspnea from poor perfusion. Because such an infant has an increased hemoglobin concentration and more oxygen is removed from the hemoglobin as a result of decreased flow, the child may be cyanotic (having more than 5 g/dL unsaturated hemoglobin) and not hypoxic. An extreme elevation of leukocyte or platelet counts can also cause blood hyperviscosity and dyspnea.

Children with anemia, even though they may have tissue hypoxia and be dyspneic, are usually not hypoxemic; that is, the arterial oxygen tension measured by blood gas analysis is in the normal range.

### Metabolic Disease

Disorders that increase the body's rate of metabolism and therefore oxygen consumption can cause dyspnea. Examples are hyperthyroidism and fever. Metabolic disorders associated with an increased production of hydrogen ion and carbon dioxide cause a dyspnea-like breathing pattern to help rid the body of the carbon dioxide. The classic example is Kussmaul breathing with diabetic ketoacidosis. Aspirin poisoning can be characterized similarly. In addition, children who have various muscle enzyme deficiencies, especially those affecting the mitochondria, may have dyspnea as a result of their increased acid production and decreased work tolerance. In chronic renal failure the kidney's inability to remove acid from the blood adequately is the underlying cause of dyspnea. The history, physical examination, and appropriate laboratory tests should facilitate the proper diagnosis of these diseases.

If oxygen cannot reach the tissues, then the body responds with dyspnea, cardiovascular collapse, and shock.

### Obesity

Dyspnea, especially with exertion, is a common complaint of obese children because their metabolic

requirement for a given amount of work is increased. In addition, the diaphragm of an obese child must move against increased abdominal pressure, and the chest wall is heavier; thus, more energy must be expended to maintain  $\dot{V}_E$ .

Asthma does not seem to play an important role as a cause of dyspnea in obese individuals. Although obesity is a risk factor for self-reported asthma, bronchodilator use, and dyspnea on exertion, obese individuals have a lower risk of objective airway obstruction as compared with persons who are not obese.

Treatment of dyspnea in obesity should include dietary regulation and an exercise program graded to keep pace with the child's level of exercise tolerance.

### Pregnancy

Dyspnea is normal during pregnancy and occurs during the first or second trimester. Seventy-six percent of women complain of dyspnea by the 31st week of gestation. The sensation reflects a subjective awareness of the hyperventilation normally present during pregnancy.

The normal dyspnea of pregnancy can be differentiated easily from dyspnea arising from heart or lung disease. The woman who has dyspnea of pregnancy has no other symptoms of cardiac or pulmonary disease. Furthermore, dyspnea of pregnancy begins early and plateaus or improves as term approaches, while dyspnea resulting from heart disease begins during the second half of pregnancy and is worst during the seventh month. Finally, dyspnea of pregnancy is rarely severe, rarely occurs at rest, and does not interfere with the activities of daily life.

### Intravenous Drug Use

Several causes of dyspnea must be considered in patients with a history of intravenous drug use. Heroin can cause bronchospasm that responds to bronchodilator medications. In addition, heroin and other opioids may precipitate pulmonary edema. Therapies consist of oxygen, diuretics, and naloxone.

Infections also may cause dyspnea in intravenous drug users. The most common infection is community-acquired pneumonia. However, opportunistic pulmonary infections, tuberculosis, and bacterial endocarditis with associated septic pulmonary emboli or heart failure must be considered.

Finally, talc granulomatosis, which can lead to chronic mild to moderate dyspnea, must be considered. It is caused by intravenous injection of dissolved opioid tablets, with deposition of foreign bodies in the pulmonary vasculature and granuloma formation.

### Psychogenic Cause

Stress or hysteria may cause dyspnea. A complete history and thorough physical examination are keys to the diagnosis. Affected patients are tachypneic and complain of air *hunger*. When dyspnea is caused by pulmonary or cardiac conditions, the shortness of breath worsens with increasing activity and improves with rest. However, the dyspnea associated with hysteria does not improve with rest and may worsen. Affected patients also often complain of chest pain and sigh more frequently than normal. Contrary to previous belief, tetany is an uncommon accompaniment of hysterical dyspnea.

Findings on physical examination are usually normal. However, stress-induced paradoxical adduction of the vocal cords during inspiration has been reported. Patients with this disorder may have either stridor or wheezing. In this instance the diagnosis of hysterical dyspnea is one of exclusion, and it can be made only after pathological lesions in the airways and lungs have been ruled out.

In most instances, the only laboratory abnormality found with hysteria-induced dyspnea is a diminished arterial carbon dioxide tension.

Treatment consists of calm reassurance and, occasionally, mild sedation. If the condition is chronic, then interventions to reduce stress and gain insight into the cause of the dyspnea, such as psychotherapy and hypnosis, may be required. When paradoxical vocal cord motion is the cause, the patient should also be taught laryngeal relaxation techniques.

## MANAGEMENT

Severe acute dyspnea is a medical emergency. If not treated promptly, a child who has dyspnea may then progress rapidly to respiratory failure and death. First, the adequacy of the airway must be assessed. Foreign bodies must be removed and anatomic obstructions bypassed with endotracheal intubation or, in rare cases, tracheotomy. Bronchospasm, when present, should be treated with beta-agonistic drugs.

Subsequently, the efficacy of the child's ventilation must be evaluated. Normally, breathing uses 2% to 3% of the total body energy expenditure. When the work of breathing is increased during dyspnea, this amount may rise to 30% or more. Such a degree of energy expenditure cannot be continued indefinitely, and the child tires. Even after an obstruction is removed, the child may still be unable to effect adequate ventilation. In this instance, or in the case of neuromuscular disease, the child requires either noninvasive positive pressure ventilation or intubation and mechanical ventilation.

Once ventilation is established, the cardiovascular system's ability to deliver oxygen to the tissues must be appraised by evaluating the heart, peripheral circulation, intravascular volume status, and the blood's oxygen-carrying capacity. Therapy with vasopressors, fluids, blood transfusions, or diuretics should be initiated when indicated. Although not all children who have dyspnea require supplemental oxygen, every child should have oxygen administered until the cause of the dyspnea is known. Once the patient's condition has stabilized, the search for the underlying cause of the dyspnea should progress urgently, but calmly. At this point, a detailed history can be elicited, a full physical examination performed, and a chest radiograph and appropriate blood tests obtained. When the diagnosis is made, specific therapy can be initiated.

When dyspnea is caused by a chronic illness, no satisfactory therapy may be available to treat the underlying disease. However, simply relieving the dyspnea can significantly improve the child's functional ability and quality of life. Several modalities can be used to treat the symptom of dyspnea in a chronically ill child. Sedatives

and narcotics reduce  $\dot{V}_E$  and thereby diminish the intensity of the breathless feeling. These medications are usually administered orally or by injection. However, they also may be effective when delivered by nebulization. Beta-agonists may blunt the perception of dyspnea without affecting ventilation. Theophylline may improve diaphragmatic contractility. Continuous supplemental oxygen reduces ventilatory drive. Noninvasive positive pressure ventilation is useful in assisting fatigued or dysfunctional respiratory muscles and in keeping small airways open. Children who have chronic obstructive pulmonary disease may be taught to breathe through pursed lips, reducing respiratory rate, increasing tidal volume, and diminishing the sensation of dyspnea. Hypnosis has proved useful in some patients, and others have reported a decrease in dyspnea when seated next to an open window or a blowing fan.

Exercise and proper nutrition are helpful in maintaining or increasing inspiratory muscle mass and thereby reducing the perceived magnitude of dyspnea. Finally, because dyspnea is a subjective complaint, the psychological contribution to its perceived severity is significant. The child's emotional state, behavior, and personality must be monitored because psychosocial intervention may be indicated.

## Chapter 144

### DYSURIA

Beatrice Goilav, MD; Frederick J. Kaskel, MD, PhD

Dysuria is any discomfort with urination but particularly refers to pain or burning during urination. Generally stemming from irritation of the bladder or urethra, it is a commonly reported sensation that affects men, women, and children alike. Although dysuria can be caused by any condition associated with inflammation, irritation, or obstruction of the urinary tract, in children and adolescents it most commonly accompanies urinary tract infections (UTIs), urethritis, and chemical or traumatic irritation. Identifying the underlying cause of dysuria requires a detailed history, a careful physical examination, and a focused laboratory evaluation as needed.

### HISTORY

The younger the child, the less precise is the complaint of painful urination. Other symptoms, such as pruritus or pain in the genital or perineal area, may be more noticeable while the child is voiding and not distracted. Although dysuria may be the only complaint, it is more often accompanied by associated symptoms. Regardless of the child's age, dividing the associated symptoms into either specific urinary symptoms or nonspecific symptoms is helpful. Symptoms specific to the urinary tract include hematuria, discharge, malodorous urine, frequency, urgency, refusal to void, new-onset nocturnal enuresis, and daytime incontinence. The physician should inquire about exposure to detergents, perfumed soaps, bubble baths, or ointments and about the type of underwear fabric, any of which can irritate the mucosal lining of the urethra or bladder. A thorough history of the timing of toilet training, last occurrence of daytime accidents, nocturnal enuresis, withholding maneuvers, and constipation can help elucidate a diagnosis of dysfunctional elimination syndrome. The lack of a history of trauma may not be accurate because children often do not recall it or, in the case of masturbation or sexual abuse, may deliberately deny it. To judge the possibility of a sexually transmitted infection, adolescents should be asked about sexual activity and safety practices. A family history of nephrolithiasis should focus attention on hypercalciuria as a cause for dysuria, and a more detailed dietary history should be elicited, including intake of salt, dairy products, and vitamins.

Symptoms outside the urinary tract, such as conjunctival injection, oral and genital ulcers, arthralgia, or a generalized rash, could suggest a systemic inflammatory condition, such as Stevens-Johnson syndrome, Reiter syndrome, or Behçet disease. A history of fever suggests an infectious condition such as pyelonephritis, appendicitis, or pelvic inflammatory disease.

### PHYSICAL EXAMINATION

The presence of a fever (body temperature  $>101.3^{\circ}\text{F}$  [ $38.5^{\circ}\text{C}$ ]) can indicate inflammation or an upper UTI such as pyelonephritis; cystitis and urethritis of any cause do not usually produce significant fever. Inspection of the skin may reveal vesicles with varicella or herpes simplex, or target lesions with Stevens-Johnson syndrome, which can be accompanied by conjunctival inflammation and oral lesions. Arthritis, particularly of the knee joint, in an adolescent should raise suspicion of Reiter syndrome.

In children of any age presenting with dysuria and a history of voiding dysfunction, particularly when accompanied by a history of chronic constipation, an occult spina bifida should be excluded by careful examination of the lower back looking for midline defects, such as a sacral cyst, a fistula, or a tuft of hair. The neurologic examination should include careful evaluation of the lower extremities for strength and reflexes, and, when suspicion is raised, the bulbocavernosus reflex should be evaluated as well.

Special attention should also be paid to the abdominal examination, which may reveal a flank or suprapubic mass, suggestive of urethral obstruction. Costovertebral tenderness suggests pyelonephritis, and suprapubic tenderness often accompanies cystitis.

On inspection of the genital area, the examiner should evaluate for discharge; if present, its character should be noted. In female patients, clear discharge may be a normal finding, whereas an odorless, cottage cheese-like appearance suggests an infection with *Candida* spp. A greenish discharge, suggestive of gonorrhea, should raise the possibility of pelvic inflammatory disease if accompanied by lower abdominal tenderness. Any discharge in male patients should be considered abnormal. Scratch marks around the mucosal area in females may suggest contact dermatitis or chemical irritation. Examination should include looking for labial adhesions and a urethral prolapse, which appears as a red circumferential protrusion of the mucosa from the urethral orifice. Attention should be paid to whether or not the male patient is circumcised; if not, note whether the foreskin is age-appropriately retractable. The location and the size of the meatus should be examined for hypospadias or stenosis.

### DIFFERENTIAL DIAGNOSIS

Dysuria can be caused by any inflammation, irritation, or obstruction of the bladder or urethra, but most often it is a symptom of a common disorder of childhood and adolescence, such as a UTI, urethritis, or a chemical or traumatic injury. Table 144-1 lists infectious and noninfectious causes of dysuria. Figures 144-1 and 144-2 depict a simplified algorithm allowing the physician to establish quickly whether the cause of dysuria is infectious/inflammatory or rather chemical/mechanical in male and female patients.

**Table 144-1****Infectious and Noninfectious Causes of Dysuria**

INFECTIOUS	NONINFECTIOUS
Pyelonephritis	Dysfunctional voiding
Cystitis	Chemical irritants
Urethritis	Trauma
Vulvovaginitis	Meatal stenosis
Balanitis and balanoposthitis	Labial adhesions
Pelvic inflammatory disease	Urethral strictures
	Urethral prolapse
	Hypercalciuria

**Common Conditions****Urinary Tract Infection**

UTIs are the most common cause of dysuria in children. The localization of the infection within the urinary tract may be challenging in young children because they tend to develop systemic symptoms such as fever, vomiting, and diarrhea even in the absence of pyelonephritis. Older children, who are likely to mount a fever with pyelonephritis rather than cystitis, can report suprapubic pain with cystitis or flank and costovertebral tenderness with pyelonephritis. All children younger than 2 years and boys of all ages should be evaluated for congenital anatomic abnormalities, such as vesicoureteral reflux, after the first UTI.

**Urethritis**

Urethritis can present with dysuria accompanied by discharge or blood spotting on the child's underwear. Causes of urethritis include infection, trauma, chemical irritation, and foreign body. Infectious causes in children are uncommon. Patients suspected of having infectious urethritis should have a urethral smear and urine culture included as part of their laboratory evaluation. Sexually transmitted infections are the major cause of urethritis in adults and adolescents. The finding of *Neisseria gonorrhea* or *Chlamydia trachomatis* in a child should prompt immediate investigation to rule out sexual abuse.

**Irritants/Trauma**

Irritants such as soap, bubble baths, and laundry detergents cause mild erythema at most. Localized trauma can result from foreign bodies, masturbation, voluntary sexual activity, or sexual abuse. Bicycle accidents and other traumas usually generate more extensive injuries than isolated genitourinary lesions.

**Meatal Stenosis**

Meatal stenosis occurs relatively commonly in boys after circumcision. Typically, the urinary stream is deflected upward, and the boy has difficulty aiming. It may be accompanied by dysuria, increased frequency, and delayed bladder emptying. Consultation with a pediatric urologist is warranted.

**Dysfunctional Voiding**

Dysfunctional voiding can result from neuropathic or non-neuropathic voiding disorders. Neuropathic voiding is associated with conditions affecting the innervation of the muscles involved in coordinated micturition. Non-neuropathic voiding dysfunction encompasses all other causes of lack of coordination between the bladder, the bladder outlet, and the pelvic floor muscles. If the patient is also constipated, then the condition is referred to as *dysfunctional elimination syndrome*, which is an important cause of idiopathic urethritis in childhood; the history should focus on timing of completion of toilet training, episodes of bed wetting, and daytime incontinence.

**Uncommon Conditions****Labial Adhesions**

Labial adhesions occur in prepubertal girls and are generally asymptomatic unless they cause secondary infections. The treatment is separation of the adhesion and topical estrogens to prevent readhesion.

**Urethral Strictures**

Urethral strictures in children can be congenital or acquired. Congenital strictures are rare. Acquired strictures occur after instrumentation, trauma, or processes accompanied by inflammation with production of an exudate and secondary sclerosis. The child presents with dysuria, infection, or a weak urinary stream. The diagnosis is made by voiding cystourethrogram or cystoscopy.

**Urethral Prolapse**

Urethral prolapse is the complete protrusion of the urethral mucosa beyond the meatus in girls. Although it is rare in the general population, there is an association with young age, black race or Hispanic ethnicity, and low socioeconomic status. The cause is unclear. Patients present with dysuria, gross hematuria, or blood spotting on the underwear. Treatment includes sitz baths, antibiotics, topical estrogens, or surgical repair. Left untreated, the prolapsed mucosa can become necrotic.

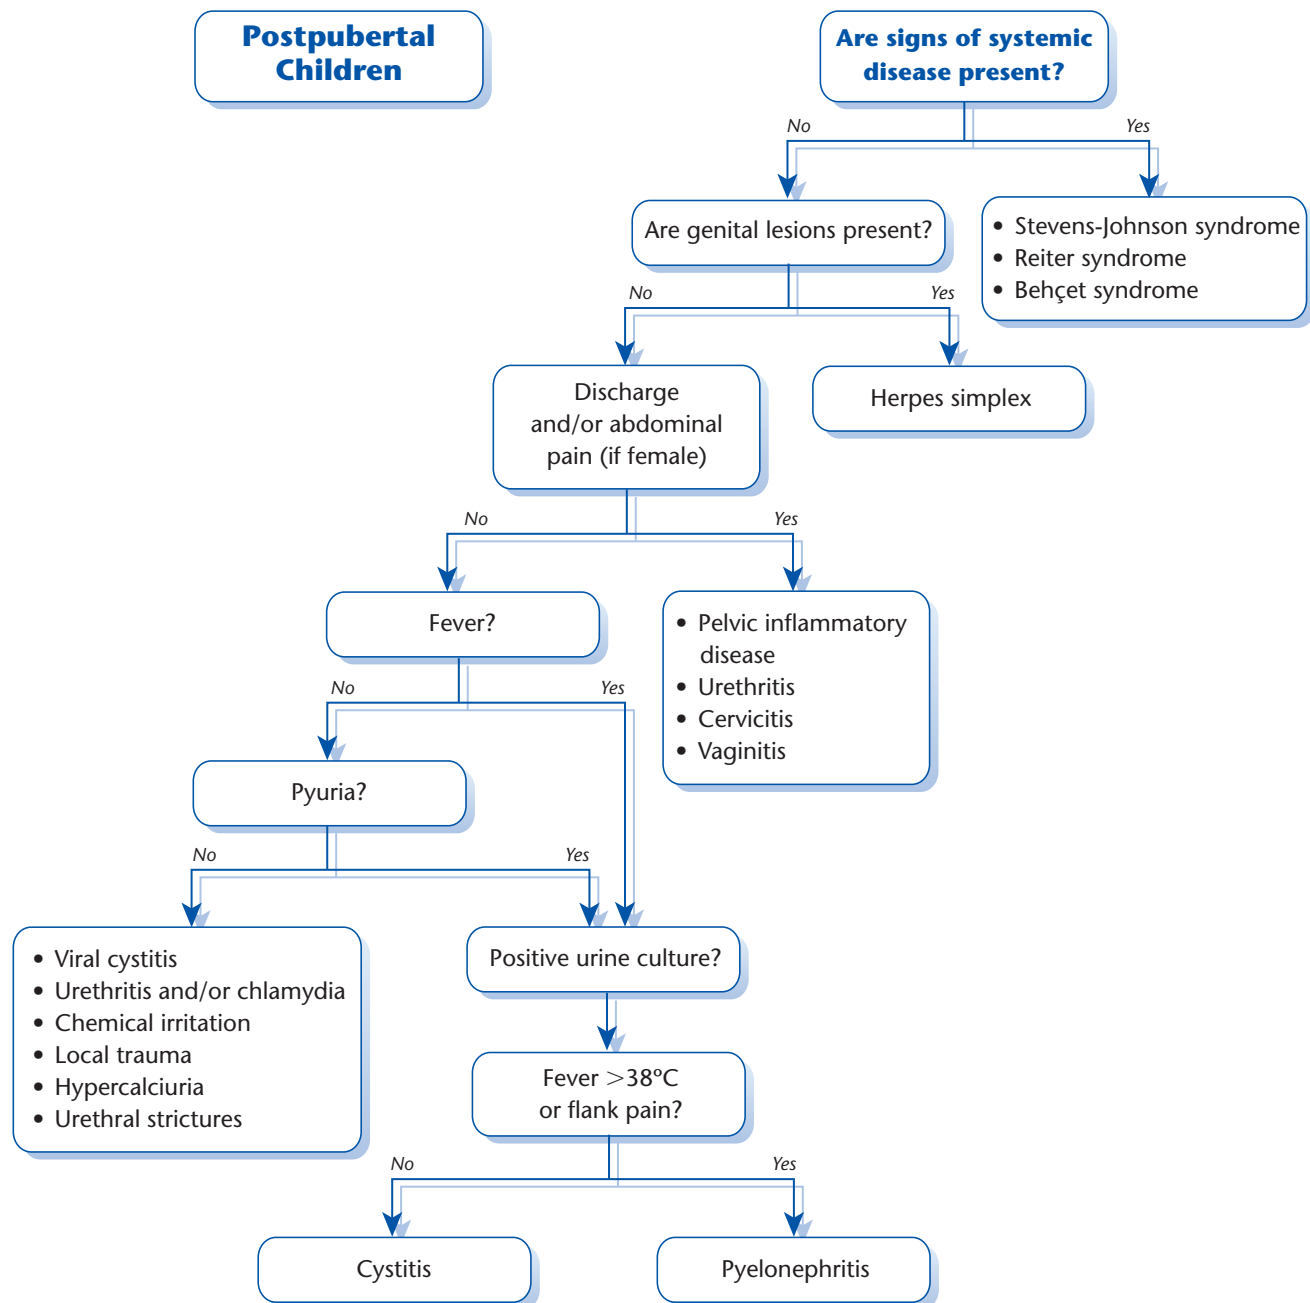

**Pelvic Inflammatory Disease**

Pelvic inflammatory disease primarily affects sexually active adolescent females, but should raise suspicion of sexual abuse in prepubertal girls. It presents with abdominal pain.

**Vulvovaginitis**

Vulvovaginitis, a rare cause of dysuria, more commonly presents with erythema of the vaginal mucosa and may be associated with discharge, which varies from clear to white to green, and may be odorless or foul smelling.

It occurs most often in sexually active adolescents, and sexually transmitted pathogens are the main cause. In prepubertal girls, the cause is often not apparent, but poor hygiene or allergies may play a role. Pathogens include local flora, such as group A streptococcus, or anaerobic bacteria, with concomitant decrease in the concentration of *Lactobacillus* spp. *Candida* spp.

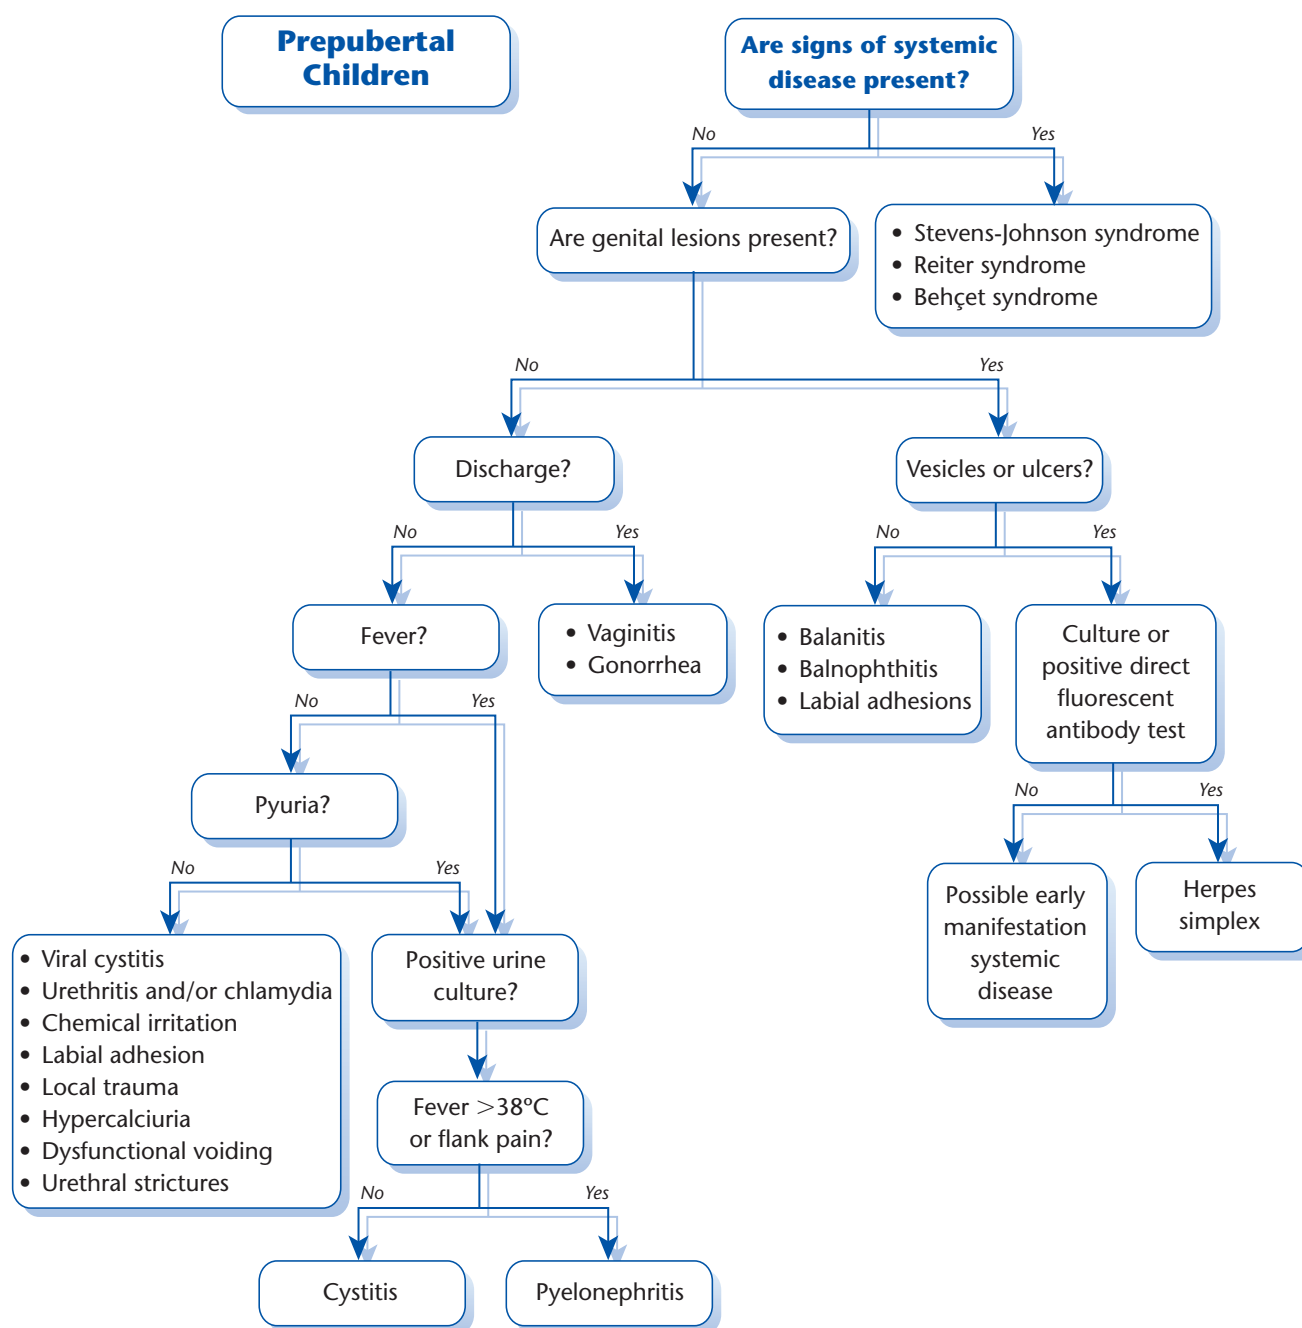

**Figure 144-1** Algorithmic approach to dysuria in postpubertal males and females. (Adapted with permission from Fleisher GR. Evaluation of dysuria in children. In: Bassow DS (ed); UpToDate, Waltham MA. Copyright © 2013 UpToDate, Inc. Available at: [www.uptodate.com](http://www.uptodate.com).)

are commonly encountered in the setting of recent antibiotic treatment or diabetes mellitus. Herpes simplex infection can present with erythema alone; the absence of vesicles or ulcerative lesions does not rule it out. When erythema of the vaginal mucosa is observed, a Gram stain and culture, KOH, and a wet prep should be sent. Any vaginal discharge should be sent for pH testing. Screening for herpes simplex should be considered.

### **Balanitis and Balanoposthitis**

Inflammation of the glans penis (balanitis) or both the glans and prepuce (balanoposthitis) occurs almost exclusively in young, uncircumcised boys with phimosis. Infection from entrapped smegma under the foreskin may result from trauma, allergies, or poor hygiene. Treatment consists of warm soaks as well as oral or local antibiotics. Topical steroids may alleviate the inflammation associated with balanitis from contact dermatitis.

**Figure 144-2** Algorithmic approach to dysuria in prepubertal males and females. (Adapted with permission from Fleisher GR. Evaluation of dysuria in children. In: Bassow DS (ed); UpToDate, Waltham MA. Copyright © 2013 UpToDate, Inc. Available at: [www.uptodate.com](http://www.uptodate.com).)

### Hypercalciuria and Urolithiasis

Urolithiasis rarely presents with dysuria, but rather is seen with flank pain and often with gross hematuria. Hypercalciuria, however, commonly manifests as dysuria caused by irritation of the uroepithelium by calcium-oxalate crystals. Patients typically have frequency, urgency, gross or microscopic hematuria, and dysuria. Examination of the urinary sediment may reveal crystals along with eumorphic red blood cells. The family history may be positive for urolithiasis.

### WHEN TO REFER

- Voiding dysfunction
- Nephrolithiasis
- Girl younger than 2 years with a UTI for the first time
- Boy of any age with a UTI or meatal stenosis
- Genitourinary tract anomalies

**WHEN TO ADMIT**

- Systemic inflammatory or infectious cause of dysuria
- Suspicion of sexual abuse

## Chapter 145

### EDEMA

Paul A. Levy, MD

At birth, as much as 70% of the newborn's body weight is water. This decreases to approximately 60% of total body weight in older children. For adolescent and adult males, total body water is even lower, with only about 55% to 60% of their body weight being made up of water, and total body water is lowest in adolescent and adult females, who have only about 50% of their body weight contributed by water. The body water is distributed into several compartments. Intracellular water represents two-thirds of the total volume. The remaining one-third is considered extracellular and is distributed between the vascular

compartment (25%) and the interstitial spaces between the cells (75%). The distribution of water in these various body compartments is tightly controlled. Failure of this control can result in the accumulation of extra fluid in the interstitium, which is *edema*.

**PATHOPHYSIOLOGIC FEATURES**

Water movement across a semipermeable membrane (osmosis) is governed by the number of particles (osmolarity) on either side of the membrane. Water moves to establish equilibrium between the 2 compartments. In blood vessels, such as capillaries, the osmolarity is generated, in part, by the electrolytes in plasma; however, because the concentrations of electrolytes in plasma and the interstitium are relatively equal, the osmotic force is largely determined by charged protein molecules, with albumin being the most predominant. The plasma proteins are referred to as *colloids*, and the osmotic force they generate is the *colloid osmotic pressure*, or *oncotic pressure*. Movement of fluid across a capillary wall is controlled by a combination of oncotic pressure, hydrostatic pressure, and the permeability of the capillary wall. The capillary oncotic pressure draws fluid into the capillary; the interstitial oncotic pressure draws capillary fluid out. The capillary hydrostatic pressure, which is related to blood pressure, is highest at the arteriole end of the capillary and drops off as blood moves toward the venule. The capillary hydrostatic force pushes fluid into the interstitium. Interestingly, systemic (arterial) hypertension does not result in edema because arteriolar sphincters protect the capillary bed from increased blood pressure. The interstitial hydrostatic pressure is related to the pressure of the fluid in the interstitium, which depends on the lymphatic drainage, the amount of fluid present in the interstitium, and the compliance of the tissue. This force counteracts the capillary hydrostatic pressure and pushes fluid back into the capillaries. Finally, the permeability of the capillary wall contributes to the leakage of fluid into the interstitium.

In normal circumstances, the interplay of these forces results in fluid exiting the capillaries at the arteriolar end and entering the capillaries at the venule end. Approximately 90% of fluid that leaves the capillaries is reabsorbed before reaching the venule. The lymphatic system returns the remaining 10%, along with its associated proteins, to the circulation.

**CAUSES OF EDEMA**

Fluid distribution between the intravascular compartment and the interstitial compartment results from the interplay of oncotic pressure, hydrostatic pressure, and capillary membrane permeability. Disruption of these forces can result in edema, but sodium concentration is usually the ultimate controller of this fluid movement (Box 145-1).

**Change in Capillary Membrane Permeability**

An increase in capillary membrane permeability is often the result of cytokines released from inflammation. Infections and burns tend to cause localized

### **BOX 145-1 Causes of Edema (Systemic or Localized as Noted)**

#### **INCREASED CAPILLARY PERMEABILITY**

- Inflammation (localized or systemic edema)
- Burns (localized edema)
- Trauma (localized edema)
- Allergic reaction (localized or systemic edema)

#### **DECREASED CAPILLARY ONCOTIC PRESSURE**

- Protein loss (nephrotic syndrome, congenital lymphangectasia, inflammatory bowel disease)
- Decreased synthesis (cirrhosis, malabsorption, malnutrition)

#### **INCREASED CAPILLARY HYDROSTATIC PRESSURE**

- Systemic venous hypertension
  - Heart failure (myocarditis, cardiomyopathy, ischemic heart disease)
  - Constrictive pericarditis
  - Note: right-sided failure results in peripheral edema, left-sided failure results in pulmonary edema.
  - Cirrhosis/liver failure
  - High output failure [anemia (ABO and Rh incompatibility), arteriovenous fistulas, hyperthyroidism]
- Localized venous hypertension (localized edema)
  - Deep vein thrombosis, compression of venous return (localized edema)

#### **INCREASED PLASMA VOLUME**

- Heart failure
- Renal failure

#### **LYMPHATIC OBSTRUCTION AND INCREASED INTERSTITIAL ONCOTIC PRESSURE**

- Lymphedema, leakage of protein into the interstitium.

edema. An allergic reaction may cause more generalized edema. Hereditary angioedema can cause localized edema of the gastrointestinal tract and larynx. Trauma causes local edema.

### **Decreased Capillary Oncotic Pressure**

A decrease in the capillary oncotic pressure can be caused by decreased levels of protein, usually of albumin in the blood. Decreased synthesis of albumin occurs in cirrhosis or as a result of malnutrition or intestinal malabsorption. Protein loss by the kidneys in nephrotic syndrome may also contribute to edema. Albumin levels below 2 mg/dL are usually associated with generalized edema. The mechanism of edema formation with decreased oncotic pressure results in extravasation of fluid into the interstitium, but it also results in poor kidney perfusion, which activates renin-aldosterone secretion and results in increased sodium reabsorption and fluid retention. This fluid may then leak into the interstitium because of the decreased oncotic pressure, compounding the edema.

### **Increased Capillary Hydrostatic Pressure**

#### **Systemic Venous Hypertension**

Systemic venous hypertension can be the result of heart failure (from cardiomyopathy, tricuspid valvular disease, or ischemic heart disease), constrictive pericarditis, or cirrhosis. In addition, high output failure (from anemia, hyperthyroidism, or arteriovenous fistulas) also leads to systemic venous hypertension. All of these conditions lead to increased capillary hydrostatic pressure and result in edema from increased extravasation of fluid into the interstitium. Left-ventricular heart failure results in pulmonary edema; right-ventricular heart failure results in venous congestion, hepatomegaly, and peripheral edema.

#### **Localized Venous Hypertension**

Localized edema may result from increased venous pressure with deep vein thrombosis or from compression of the inferior vena cava or iliac vein by a tumor. The increased venous pressure raises the capillary hydrostatic pressure.

#### **Increased Plasma Volume**

Glomerular nephritis increases plasma volume resulting from sodium retention. Renal failure can increase plasma volume from an inability to secrete sodium and water. Heart failure and liver disease (cirrhosis) result in decreased effective volume, which increases sodium reabsorption in the kidney by activation of the renin-angiotensin-aldosterone system. Sympathetic nervous stimulation can also result in increased sodium reabsorption in the kidney.

### **Increased Interstitial Hydrostatic Pressure**

Increased interstitial hydrostatic pressure, although rare, may result from lymphatic obstruction by a tumor or large lymph nodes, from damage to the lymphatic system by radiation or surgery, or from parasitic infections such as filariasis.

## **EVALUATION**

### **History**

A detailed history must be obtained to discover the cause of the edema. The time course of the edema—whether its onset is recent or chronic—is particularly important. If chronic, then the parents and child may report weight gain, tight clothing, or snug-fitting shoes, findings they may have attributed to the growth of the child. The history of a recent illness, such as pharyngitis, is important for the diagnosis of glomerulonephritis. In addition to the edema, other systemic complaints may be present, including shortness of breath, tachypnea, or cough, which may indicate the presence of heart failure and pulmonary edema. Ascites, a form of localized edema, is seen with liver failure or cirrhosis and with some congenital liver malformations. The child's nutritional status should be assessed, because malnutrition may result in hypoalbuminemia, which can, in turn, result in edema.

### Physical Examination

Edema may be generalized or localized. If localized, then it may be easily apparent when it affects an extremity (deep vein thrombosis, cellulitis, burn). If generalized, it may be more occult (pulmonary edema from left-ventricular heart failure, ascites from liver disease). Physical examination should begin with close observation of the vital signs. Tachypnea may indicate pulmonary edema. Increased blood pressure may be present in glomerulonephritis and renal failure. Fever and localized edema may be present with cellulitis.

Periorbital edema is generally found with nephrotic syndrome and glomerulonephritis. Crackles or rales may indicate the presence of pulmonary edema. A gallop may indicate heart failure. Abdominal distention, shifting dullness, or a fluid wave may be present with ascites. Generalized edema may include scrotal or labial edema. Findings related to generalized edema may depend on whether the patient has been lying down (sacral edema) or standing (feet and lower legs). Chronic edema may result in bedsores. A distinction may be made between pitting and nonpitting edema. Nonpitting edema is often the result of lymphedema, whereas pitting edema is the result of increased membrane permeability, increased hydrostatic pressure, or decreased oncotic pressure.

### Laboratory Evaluation

Initial testing may include a urinalysis, complete blood count, electrolytes with blood urea nitrogen and creatinine, liver function tests with albumin, lipid studies and cholesterol, and thyroid function tests. The results of this initial evaluation may suggest further testing. Elevated blood urea nitrogen may suggest chronic renal injury. A renal ultrasound may be warranted to look for hydronephrosis because of congenital anomalies. With proteinuria, C3, C4 and antinuclear antibody (ANA) may be indicated. If heart failure is suspected, an electrocardiogram and chest radiograph can be obtained. Testing for fecal fat is appropriate if intestinal malabsorption is suspected, and  $\alpha_1$ -antitrypsin may be helpful for diagnosing protein-losing enteropathy. With angioedema, whether hereditary or acquired, levels of C1 esterase inhibitor are low.

## INTERPRETATION OF TESTS

### Hematologic Abnormalities

Severe anemia can result in edema, especially in a newborn. The anemia can be the result of hemolysis from ABO blood type or Rh incompatibility or from glucose-6-phosphate dehydrogenase deficiency. High-output cardiac failure leads to increased capillary hydrostatic pressure, resulting in edema.

### Renal Disease

The presence of proteinuria with low serum albumin is highly suggestive of nephrotic syndrome. If red cell casts and hematuria (especially cola-colored urine) are present, then glomerulonephritis may be the cause of the edema. C3 levels may be needed to help distinguish between the types of glomerulonephritis. Low C3 suggests poststreptococcal glomerular nephritis

(PSGN) or membranoproliferative glomerular nephritis (MPGN). PSGN usually has improving C3 levels after several weeks. For nephrotic syndrome, low C3 with low C4 and a positive ANA suggest lupus nephritis. If uremia is present, a renal ultrasound may be indicated to look for dysplastic kidneys or hydronephrosis resulting from posterior urethral valves or other anatomic abnormalities. Children with undiagnosed reflux nephropathy may have severe hydronephrosis and renal failure.

### Liver Disease

Hypoalbuminemia without proteinuria suggests either a synthesis defect found with chronic liver disease or a protein-losing enteropathy. Prothrombin time, which is a good marker of the liver's ability to synthesize protein, should be assessed when hypoalbuminemia is present without proteinuria. Liver function tests may also provide helpful information. Analysis of stool  $\alpha_1$ -antitrypsin will help diagnose protein-losing enteropathy.

### Venous Thrombosis

If venous thrombosis is suspected, a Doppler ultrasound examination should be performed to assess the blood flow in the area that may be affected by the thrombosis. Clotting studies should then be conducted, especially if no predisposing factor, such as an indwelling catheter, is present.

### Enteropathy

The presence of increased fat in fecal matter strongly suggests intestinal malabsorption. Determining which intestinal disorder (cystic fibrosis, inflammatory bowel disease, milk protein allergy, enterokinase deficiency, celiac disease, or intestinal lymphangiectasia) may be the cause of the hypoalbuminemia requires further testing and consultation with a gastroenterologist.

## MANAGEMENT

Initial management involves determining whether the patient should be admitted to the hospital. Many causes of edema require admission. Patients with signs of respiratory distress that result from edema of the airway, heart failure with pulmonary edema, and tachypnea should be admitted. Renal causes, such as previously undiagnosed renal failure, acute glomerulonephritis, or nephrotic syndrome, may also require admission. Oliguria from renal failure or poor renal perfusion should result in emergent admission. Edema that results from cirrhosis may require admission if the cirrhosis had been unrecognized or if respiratory distress resulting from the ascites is present. Localized edema that results from venous thrombosis or lymphatic obstruction requires admission to assess and treat the underlying cause. Further management depends on the underlying cause of the edema.

### Anemia

Severe anemia may need to be treated with transfusion. A hematologist should be consulted if the cause of the anemia is not readily apparent.

### Renal Disease

Most patients with renal disease benefit from a low-sodium diet. Fluid restriction may help, but it should be used cautiously on an individual-patient basis in consultation with a nephrologist. Diuretics may also be needed but should be used cautiously. If plasma volume is decreased, then fluid expansion with colloid followed by diuretics may be necessary.

### Liver Disease

A low-sodium diet is generally helpful if ascites is present. Diuretics, especially spironolactone, may also be beneficial. When possible, treating the underlying cause of the ascites is critical.

### Heart Disease

Treating heart failure may require inotropic medications such as digoxin or dobutamine. An angiotensin-converting enzyme inhibitor may help with afterload reduction. If congenital heart disease is causing the heart failure, then surgical repair of the underlying structural lesion is the ultimate treatment.

### Venous Thrombosis

When a venous thrombosis is present, anticoagulation therapy may be indicated. Consultation with a hematologist and possibly a vascular surgeon may be necessary. In the absence of an obvious predisposing factor, investigation for an underlying coagulopathy is appropriate.

### Enteropathy

Treatment depends on the cause of the enteropathy. A gastroenterologist should be consulted.

### Myxedema

Generally, myxedema is found with hypothyroidism and responds to treatment with thyroid hormone replacement.

## SUMMARY

Edema is the accumulation of fluid in the interstitial tissues resulting from disruption of the forces that control normal fluid movement out of and into capillaries and may be the result of many different disease states. The underlying cause is generally apparent, although sometimes subtle. Intervention may initially need to be supportive, but once a patient is stable, efforts to treat the underlying cause of the edema should be pursued, often with the help of a specialist.

### WHEN TO REFER

Many disorders that cause edema may require the assistance of a specialist. A referral to a specialist should be considered if evidence exists of

- Liver disease (ie, ascites)
- Renal disease (glomerulonephritis, nephrotic syndrome)
- Anemia
- Protein-losing enteropathy or increased fecal fat with malabsorption and secondary hypoalbuminemia
- Heart failure

### WHEN TO ADMIT

Many of the causes of edema are serious medical problems that often require admission. This approach may initially be for support. Once a diagnosis is established and the patient is stable, further treatment usually continues on an outpatient basis with the assistance of a specialist. Signs of any of the following may require admission:

- Respiratory distress
- Heart failure
- Tachypnea
- Renal failure
- Acute glomerulonephritis or nephrotic syndrome
- Oliguria from renal failure
- Edema caused by previously unrecognized cirrhosis
- Localized edema that results from venous thrombosis or lymphatic obstruction
- Anemia severe enough to require a transfusion

## Chapter 146 EPISTAXIS

Miriam Schechter, MD; David M. Stevens, MD

Epistaxis, from the Greek *epistazō*, to bleed at the nose (from *epi*, on, + *stazō*, to fall in drops) is defined as acute bleeding from the nostril, nasal cavity, or nasopharynx. A nosebleed is a relatively common and usually self-limited occurrence in childhood; however, when profuse or recurrent, it can be extremely distressing to children and parents and can at times be a sign of a more serious condition.

### EPIDEMIOLOGIC FACTORS

The incidence of epistaxis has a bimodal distribution with peaks in children younger than 10 years and in adults older than 50 years. It is more common in boys and men than it is in girls and women. From 5% to 14% of Americans have a nosebleed each year, and approximately 10% of them seek care from a physician. Although common in children, epistaxis is rare before the age of 2 years, peaks between the ages of 3 and 8 years, and is uncommon after puberty. Nosebleeds also are more common in children living in dry

climates and occur more often in winter months. Approximately 30% of children from birth to age 5, 56% of children aged 6 to 10, and 64% of children aged 11 to 15 have had at least 1 nosebleed in their lifetime. In a study of the epidemiology of epistaxis in US emergency departments from 1992 to 2001, approximately 1 in 200 emergency department visits were for epistaxis. Peaks were found in children younger than 10 years and in older adults between the ages of 70 and 79. A higher proportion of emergency department visits occurred during the winter months, and 83% of cases were from atraumatic causes.

## DEFINITIONS AND ANATOMIC FEATURES

Nosebleeds are usually classified as anterior or posterior based on the location of the vessels that are the source of the bleed. The blood supply to the nose originates in both the internal and the external carotid arteries (Figure 146-1). The ophthalmic branch of the internal carotid gives off the anterior and posterior ethmoid arteries, which supply the superior nasal septum and the lateral nasal wall. The internal maxillary and facial arteries, which are branches of the external carotid, further divide to supply the nose. The internal maxillary artery splits into the sphenopalatine artery, the posterior nasal artery, and the greater palatine artery, and the facial artery gives off the superior labial artery. The branches of the sphenopalatine provide blood flow to the turbinates laterally and the anterior and posterior septum, the greater palatine supplies the anterior septum, and the superior labial artery supplies the anterior nose and anterior nasal septum.

The anastomoses of vessels in the anterior 2 to 3 cm of the nasal septum, just 0.5 cm from the tip of the nose, also known as Little area, make up Kiesselbach plexus, the primary source of anterior nosebleeds. The delicate vessels that comprise Kiesselbach plexus include the septal branches of the anterior ethmoid, sphenopalatine, greater palatine, and superior labial arteries. These vessels are superficial because the nasal mucosa is

closely adherent to the perichondrium and periosteum. Posterior bleeds usually originate in Woodruff plexus, a convergence of the sphenopalatine, posterior nasal, and ascending pharyngeal arteries, located over the posterior middle turbinate. Specifically, the sphenopalatine is the most frequent source of posterior epistaxis.

Anterior bleeds are by far the most common type, accounting for greater than 90% of epistaxis in children. The rich vasculature under the thin mucosa in the area most exposed to trauma and dry air makes Kiesselbach plexus the most vulnerable to bleeding. During anterior epistaxis, almost all the blood exits anteriorly through the nares. However, with posterior epistaxis, most of the blood flows into the nasopharynx and mouth, making the degree of bleeding difficult to assess. Anterior bleeds are therefore much easier to visualize and easier to control than posterior bleeds, which are generally much more profuse and are more likely to lead to hemodynamic instability.

## DIFFERENTIAL DIAGNOSIS

The causes of epistaxis can be categorized into local and systemic causes (Box 146-1). More than 1 factor often plays a role in the bleeding.

Trauma from nose picking or nose rubbing accounts for most cases in children, particularly in association with inflammation from infection or allergy. Epistaxis from blunt external trauma is generally acute and self-limiting, but could result from child abuse in very young children. Trauma from a foreign body is an occasional cause in toddlers, often resulting in unilateral bleeding accompanied by foul-smelling or bloody discharge.

Upper respiratory infection and allergic rhinitis are commonly associated with childhood epistaxis. The resultant rhinorrhea leads to digital manipulation or forceful sneezing and nose blowing, and the vascular congestion and mucosal irritation promote easy injury to the blood vessels of the anterior septum. Positive allergy skin tests and recurrent epistaxis are associated in children.

**Figure 146-1** Blood supply to the nose (septum and lateral wall).

    - Polyps
    - Hemangiomas
    - Juvenile nasopharyngeal angiofibroma
  - Malignant
    - Nasopharyngeal carcinoma
    - Rhabdomyosarcoma
- Nasal septal deviation
- Intranasal drugs
  - Steroids
  - Cocaine

**SYSTEMIC**

- Bleeding disorders
  - Thrombocytopenia
    - Immune thrombocytopenic purpura
    - Leukemia
  - Platelet dysfunction
    - Bernard-Soulier syndrome
    - Aspirin; nonsteroidal anti-inflammatory drugs
  - Coagulopathies
    - von Willebrand disease
    - Hemophilias
    - Liver disease
- Vascular abnormalities
  - Hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome)

Exposure to low environmental humidity, especially in winter months, has clearly been associated with an increased frequency of nosebleeds. A deviated nasal septum can contribute to recurrent epistaxis by causing a change in normal airflow, leading to mucosal drying and irritation. Colonization with *Staphylococcus aureus* leading to chronic inflammation and neovascularization may contribute to recurrent episodes.

Neoplasms (benign or malignant) are uncommon causes of epistaxis in children but should be considered in certain circumstances. Polyps in children are usually associated with cystic fibrosis. Juvenile nasopharyngeal angiofibroma is a benign vascular tumor originating in the lateral nasopharynx that occurs only in male adolescents because of its hormonal sensitivity. Although unilateral progressive obstruction or discharge

are clues to this diagnosis, recurrent epistaxis is the most frequent presenting complaint in these patients. Rhabdomyosarcoma of the nasal cavity or nasopharynx is a rare malignant cause of severe episodic epistaxis and may be associated with signs of eustachian tube dysfunction such as unilateral middle ear effusion. Nasal hemangioma is also a rare cause of epistaxis but should be considered in infants. Nasopharyngeal carcinoma is an extremely uncommon but serious disease in children; epistaxis is the presenting complaint in approximately 50% of cases, although it is nearly always accompanied by a neck mass or neck pain.

Systemic causes of epistaxis should be considered whenever nosebleeds are recurrent or persistent in the absence of any obvious local cause. Hematologic disorders include platelet disorders and coagulation defects and may be either congenital or acquired. Thrombocytopenia as a cause of epistaxis is almost always accompanied by petechiae or ecchymoses. The most common cause of isolated thrombocytopenia in otherwise healthy children is immune thrombocytopenic purpura, which presents as acute mucosal hemorrhage, often epistaxis, in approximately 30% of patients, although the bleeding is rarely severe. By contrast, epistaxis rarely is the first symptom of leukemia, but this diagnosis should be considered in an ill-appearing child with epistaxis, especially with fever, pallor, lymphadenopathy, or hepatosplenomegaly. Thrombocytopenia can also be an adverse reaction to a variety of medications, including anticonvulsants such as carbamazepine and chemotherapeutic agents.

Platelet dysfunction from aspirin or nonsteroidal anti-inflammatory drugs can also predispose the individual to epistaxis. Bernard-Soulier syndrome, a disorder of platelet adhesion, is an occasional diagnosis in children evaluated for isolated epistaxis. Primary coagulation defects may result in persistent and long-standing epistaxis; a positive family history is often present. Up to one-third of children with isolated recurrent epistaxis have a diagnosable coagulopathy. Von Willebrand disease (vWD) is the most commonly identified inherited coagulopathy. In fact, 60% of patients with vWD suffer from recurrent epistaxis; other mucosal bleeding (eg, menorrhagia or postsurgical or postdental extraction) is also a common complaint in older children and adolescents. Much less common are the hemophilias, which in mild cases may cause isolated epistaxis (factors VII, VIII, IX or XI deficiency).

Acquired coagulopathies are a rare cause of epistaxis in children, unlike adults, but include various liver diseases (eg, chronic active hepatitis) with consequent depletion of clotting factors. In addition, an acquired form of vWD has been described in children receiving valproic acid.

Hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome) is an autosomal-dominant disorder of blood vessel walls characterized by the progressive development of cutaneous and mucosal telangiectasias. More than 90% of affected patients have recurrent and progressively worsening epistaxis, presenting at a mean age of 12 years, although gastrointestinal bleeding and pulmonary arteriovenous malformations also occasionally occur in childhood. Primary isolated hypertension has not been clearly

associated with epistaxis in children, except in the context of renal failure. Finally, 1 recent study has shown a significant association between migraine headaches and recurrent epistaxis, suggesting a common pathogenesis.

## EVALUATION

The evaluation of children with epistaxis should begin with a careful history and physical examination. The season and associated environmental conditions should be noted. The degree of chronicity may suggest an inherited systemic cause. Unilaterality may suggest a local anatomic cause. A history of nose picking or blunt trauma should be sought. One-half of children treated in an emergency room for intranasal foreign body admitted placing the object in the nose; therefore young children should be questioned. A family history of bleeding symptoms or diagnosed disorder is useful in identifying children with a bleeding diathesis.

Associated symptoms should be sought. Unilateral progressive obstruction suggests a mass. The presence and character of any associated rhinorrhea should be noted. Clear, watery rhinorrhea with associated sneezing suggests allergic rhinitis, and mucoid discharge with cough suggests upper respiratory infection. Unilateral foul smelling discharge in a young child may indicate a retained foreign body. A history of petechiae or easy bruising or other mucosal bleeding (eg, menorrhagia, postsurgical) may point to a bleeding disorder. Associated fever or pallor may suggest leukemia. A history of medication use, particularly of aspirin or nonsteroidal anti-inflammatory drugs, should be sought.

The physical examination should include a blood pressure and pulse if the history suggests significant acute or chronic blood loss. A careful examination of the nose should include an attempt to identify the source of any active bleeding (see Management later in this chapter) and to note any discharge, obstructing mass, or foreign body. The skin should be checked for petechiae or unusual location or number of ecchymoses. The neck should be examined for the presence of a mass. If the child is ill, a full examination, including a search for lymphadenopathy and hepatosplenomegaly, should be performed.

The need for and extent of laboratory testing should be guided by the history and physical examination. Frequent and prolonged episodes may warrant ruling out anemia caused by blood loss. Persistent or recurrent epistaxis in the absence of an obvious cause may warrant testing to search for an underlying pathologic condition. A complete blood cell count (CBC) is always indicated in the presence of petechiae or unusual ecchymoses to rule out thrombocytopenia. In an ill child with pallor, fever, lymphadenopathy, or hepatosplenomegaly, a CBC will help rule out leukemia.

The frequency, duration, amount, age at onset, and site of epistaxis have been used in an epistaxis scoring system (Table 146-1) to determine which patients should be evaluated for an underlying bleeding disorder. Use of another pediatric bleeding questionnaire revealed that epistaxis of long duration, lacking seasonal correlation, and requiring medical intervention to stop was

<sup>c</sup>Proportion of the child's life that nosebleeds had been recurrent (>5/yr). From Katsanis E, Luke K, Hsu E, et al. Prevalence and significance of mild bleeding disorders in children with recurrent epistaxis. *J Pediatr*. 1988;113:73–76. Copyright © 1988, Elsevier, with permission.

significantly associated with vWD. This is especially true if the child has bled excessively following circumcision, dental extraction, or with menses. Age younger than 1 year or the need for cauterization have been suggested as reasons to perform an evaluation. Prothrombin time and partial thromboplastin time are useful as initial screening tests. However, given that these results may be within the normal range in some patients with vWD, further evaluation with von Willebrand factor studies may be necessary. If this relatively common coagulopathy is being considered or a platelet dysfunction disorder is suspected, then referring the patient to a hematologist may be prudent.

Rarely, imaging studies are indicated, but plain films can rule out an associated fracture of the facial bones in the setting of blunt trauma. In children younger than 2 years, a child abuse evaluation for inflicted trauma may be warranted. If a mass is thought to be present, then a computed tomography scan or referral to an otolaryngologist should be made.

## MANAGEMENT

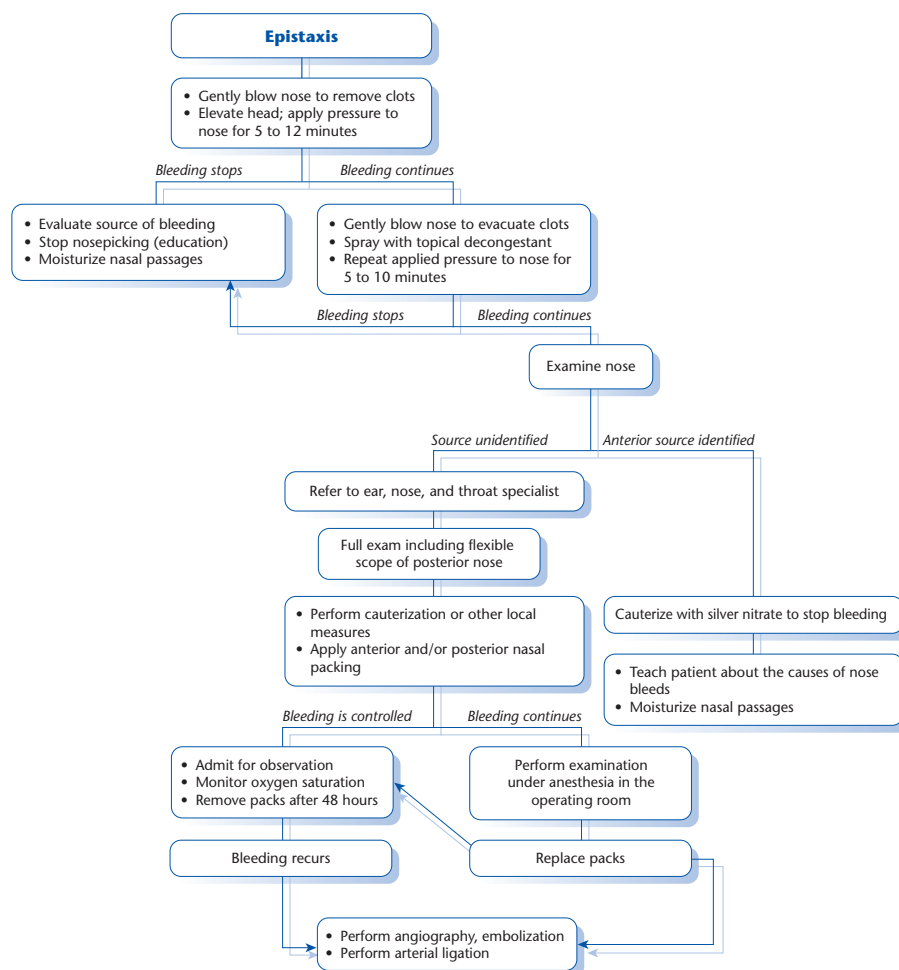

Management of nosebleeds can be divided into 3 general phases. The initial first aid measures that often are performed at home should also be the first line of treatment on presentation to the physician. Next is the acute management of persistent bleeding, which may be initiated by a pediatrician in an office or emergency department but may have to be continued by an

otolaryngologist if initial measures are unsuccessful. This phase may involve medical or surgical intervention, or both (Figure 146-2). Finally, long-term preventive treatment of recurrent epistaxis is necessary, including evaluation and treatment of underlying causes. Although most episodes of epistaxis in childhood are self-limited, they create parental concern and anxiety, and pediatricians must therefore be aware of the treatment options.

Many physicians and patients are unaware of the proper spot for applying direct pressure to the nose to stop a nosebleed. Given that most bleeds originate anteriorly, in Little's area, the first step is to apply pressure to the alar nasi using the first and second fingers. Pressure should be held by pinching the nostrils without interruption for 5 to 10 minutes. The child should sit up with the head bent forward slightly, to minimize blood dripping posteriorly and being swallowed, which can cause nausea and hematemeses. Some physicians suggest placement of ice packs to the forehead, bridge of the nose, nape of the neck, or upper lip to promote vasoconstriction, although only theory supports this practice.

In the health care setting, initial treatment measures should occur simultaneously with assessment and history taking. Basic equipment should be readied (Box 146-2). Most anterior nosebleeds in children will stop after basic first aid. However, if bleeding persists, then additional measures are available. As in any acute situation, an initial CAB (Circulation, Airway, Breathing) assessment should be made. Evaluation for major hemorrhage includes evaluating for tachycardia, hypotension, and orthostasis. Although uncommon in children, airway compromise or hemodynamic instability (or both) requires emergency management.

A history should quickly be obtained (see discussion under Evaluation earlier in this chapter) and an attempt made to locate the source of bleeding. The bleeding has often stopped by the time medical attention is sought. The child should be asked to blow out all clots. If this is not possible, then blood in the nose can be suctioned out. To try to visualize the source of bleeding, 1 of the following 3 tools could be used: a flashlight, while applying gentle upward pressure to the nasal tip; an otoscope with speculum; or a headlight and nasal speculum. Because the anterior septum

**Figure 146-2** Treatment of epistaxis. (From Rudolph AM, Rudolph CD, Hostetter MK, et al, eds. Rudolph's Pediatrics. 21st ed. New York, NY: McGraw-Hill; 2003. Reprinted by permission of The McGraw-Hill Companies, Inc.)

is the most common location of epistaxis in children, this area should be inspected first. Anterior bleeds on the septum, or lateral wall, should be evident by active bleeding, clots, crusts, ulcerations, or prominent blood vessels. If an anterior source is not found and a posterior bleed is thought to exist, then an otolaryngologist should be consulted immediately because posterior bleeds are usually profuse and difficult to stop. Luckily, posterior bleeds are rare in children. If an anterior bleed has not ceased with application of pressure alone, then topical vasoconstrictors (Box 146-2) can be applied with a cotton pledget to shrink the nasal mucosa to improve visualization and possibly to slow down or even stop the bleeding. Use of topical thrombin may also help promote hemostasis. Pressure, again by pinching, should be applied for another 5 to 10 minutes.

The next step to attempt to stop persistent hemorrhage is chemical cauterization, with silver nitrate on applicator sticks. First, local anesthesia should be administered (Box 146-2) with a cotton pledget for 5 minutes to reduce the discomfort of cauterization.

### **BOX 146-2 Equipment Used in the Initial Management of Anterior Epistaxis**

#### **EXAMINATION**

- Flashlight *or*
- Otoscope with speculum *or*
- Headlight and nasal speculum
- Suction

#### **TOPICAL VASOCONSTRICTION**

- Oxymetazoline 0.05% (Afrin) *or*
- Phenylephrine 0.25%, 0.5% (Neo-Synephrine) *or*
- Epinephrine 1:1,000 *or*
- Cocaine solution 3%–5%

#### **TOPICAL ANESTHESIA**

- Lidocaine 4% *or*
- Cocaine solution 3%–5% *or*
- Ethyl chloride

#### **HEMOSTASIS**

- Silver nitrate sticks
- Vaseline strip gauze
- Oxycellulose sponges (Surgicel) *or*
- Gelatin sponges (Gelfoam) *or*
- Nasal tampons/expandable nasal pack (Merocel, RhinoRocket)

#### **ADDITIONAL ITEMS**

- Antibiotic ointment or cream (Naseptin; note: contains peanut oil)
- Cotton pledgets, gauze
- Gown, gloves, mask

After inserting and opening a nasal speculum, using adequate lighting, the silver nitrate is applied to the bleeding point and can be rolled over the site for 5 to 10 seconds. The procedure may have to be repeated 2 to 3 times to achieve hemostasis. Silver nitrate does not work well in pools of blood; therefore, suction may be necessary to keep the area dry. A gray eschar will form at the cautery site. Excess silver nitrate should be removed with cotton or gauze to minimize dispersion by nasal secretions and resulting injury to intact mucosa. Caution should be used to avoid cauterizing too large or too deep an area and to avoid cauterizing both sides of the septum because these measures can lead to septal perforation. After cauterization, the physician should prescribe antibiotic cream or ointment to apply to the area twice a day for 5 days to prevent crusting and infection. Hydration with saline or ointment should continue until healing is complete, in approximately 1 to 3 weeks. Nasal trauma and forceful nose blowing should be avoided during this time. Otolaryngologists may use electrocautery as another hemostatic measure. This type of thermal cautery, however, cannot be performed with topical anesthesia alone.

If an anterior bleed persists despite direct pressure or nasal cautery, then anterior nasal packing may be required. This task can be accomplished with antibiotic impregnated petroleum jelly gauze, which is layered into the anterior nose and provides a tight pack. However, packing is uncomfortable and may require procedural sedation, requires subsequent removal (usually after 2 to 3 days), and can cause additional mucosal injury. Oxycellulose or gelatin sponges are absorbable and do not require later extraction. Although they do not apply a great deal of pressure to the bleeding site, these types of packing are usually adequate for most nosebleeds. Commercially available nasal tampons made of a dehydrated polyvinyl polymer sponge can also be used. The tampons are inserted dry and then expand with blood or added saline partially to fill the nasal cavity. These products come in many sizes and can be cut to fit a child's nasal cavity. They must be removed, usually after 3 to 5 days, and have a tendency to adhere to the nasal lining.

All types of packing and sponges should be impregnated or coated with antibiotic ointment to prevent toxic shock syndrome, which is a reported complication of anterior and posterior nasal packing. Although no clear evidence exists to prove that prophylactic antibiotics reduce the incidence of serious infection, studies have shown that they reduce gram-negative bacterial growth, and common practice is to prescribe them for any patient with nasal packing. Antibiotics, such as amoxicillin-clavulanate, may also help prevent sinusitis that can result from stasis of nasal secretions when packing is in place.

Identification of the source of a posterior bleed must be done by an otolaryngologist using a flexible fiberoptic nasopharyngoscope; sedation may be required for younger patients. In addition to locating a superior or posterior bleeding site, endoscopic visualization may also reveal causes such as foreign bodies, tumors, or sinusitis. In older, more cooperative patients, a rigid endoscope may be used. Cauterization

of a posterior bleeding site can be performed under general anesthesia. Posterior packing can be done with gauze or even urinary catheter balloons. Other types of packing include premade nasal tampons or balloons. All patients requiring posterior packing need sedation and must be admitted to the hospital and monitored in an intensive care unit for airway obstruction and respiratory compromise. More invasive measures such as arterial embolization for refractory bleeds and arterial ligation for recurrent epistaxis are rarely indicated in children.

Once the acute episode of epistaxis has resolved, attention can be focused on looking for predisposing factors or causes and respective preventive strategies or specific management. If a dry environment is present, then the use of normal saline nasal spray helps to humidify the nasal cavity. The spray should be used 4 to 5 times a day. A humidifier in the home may also be useful. The increased moisture helps prevent the accumulation of crusts, which are often the impetus for nose-picking, and keeps scabs soft, allowing them to stay in place longer and thus promoting healing of underlying mucosal injury. Local trauma should be minimized by discouraging nose-picking, forceful rubbing, or blowing of the nose. Fingernails can be trimmed as well. Parents should be educated about the home management of an acute nosebleed; they should pinch the nasal tip for 5 to 10 minutes with the child sitting up, leaning slightly forward.

If allergic rhinitis is a factor in epistaxis, then appropriate testing and medical management is indicated, including treatment with oral antihistamines or inhaled topical nasal steroids. For sinusitis, oral antibiotics are prescribed. If a bleeding disorder is thought to exist, then laboratory workup (see discussion under Evaluation earlier in this chapter) or referral to a hematologist is warranted. Otolaryngologists treat other uncommon lesions and conditions. For example, they will cauterize granulomas, monitor hemangiomas, and excise juvenile nasopharyngeal angiofibromas after hormonal therapy and embolization. Patients with hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome) are now treated with argon laser therapy along with septal dermoplasty.

A common challenge for physicians is the management of recurrent nosebleeds. A recent Cochrane review of the literature on interventions for recurrent idiopathic epistaxis in children exposed the lack of evidence for current treatments of this problem. The condition was defined as repeated nasal bleeding in patients younger than 16 years without identifiable cause. Consensus does not exist on the frequency or severity of the episodes of epistaxis that warrant medical intervention. However, common interventions for less severe cases include cautery with silver nitrate, application of antibiotic nasal creams, instillation of nasal saline spray, or coating the interior nose with ointments such as petroleum jelly. Less commonly advocated topical agents include oxymetazoline, desmopressin, antifibrinolytics, and, most recently, fibrin sealants. On review of the few studies that have been done, no single treatment (neomycin-chlorhexidine antiseptic cream, silver nitrate cautery, petroleum jelly) was found to be superior to another or to no treatment

at all. No serious adverse effects were experienced, although silver nitrate cauterization caused pain in children despite topical anesthesia. One small study suggested that cautery combined with antibiotic cream is more effective than cream alone. Also, if cautery is used, 75% silver nitrate has been shown to be more effective in the short term (but not long term) and caused less pain for the children than 95%. High-quality studies, with longer follow-up, are needed to ascertain which, if any, of these remedies for recurrent epistaxis in children are most optimal.

Nosebleeds occur commonly in children. Although quite upsetting and worrisome to parents, most epistaxis in childhood is anterior, is controlled by simple first aid measures, and results from benign causes. Epistaxis is therefore usually treated on an outpatient basis by general pediatricians. An understanding of all potential causes and acute and long-term management of nosebleeds will assist the pediatrician in appropriate treatment of this condition.

### WHEN TO REFER

#### Ear, Nose, and Throat

##### *Urgent Referral*

- Profuse, uncontrollable bleeding
- Inability to locate source of bleed
- Posterior bleeding
- Assistance with anterior packing
- Recurrence of bleed after initial emergency department measures

##### *Nonurgent Referral*

- Removal of anterior packing
- Recurrent epistaxis
- Evaluation for structural lesions (ie, granulomas, tumors, polyps)
- Treatment of specific lesions

#### Hematology

- Abnormal CBC or coagulation laboratory profile
- Severe, persistent, or recurrent bleeding
- Bleeding from more than 1 site, based on history or physical examination
- Bleeding that required blood transfusion or iron therapy
- Family history of coagulopathy

### WHEN TO ADMIT

- Hemodynamic instability on presentation
- Posterior nasal packing in place

### TOOLS FOR PRACTICE

#### Engaging Patient and Family

## Chapter 147 EXTREMITY PAIN

Michael G. Burke, MD, MBA; David C. Hanson, MD

### DEFINITION OF TERMS

Extremity pain is a common complaint in primary care pediatric practice. Up to 16% of school-aged children report at least 1 episode of activity-limiting extremity pain annually. Among surveyed 8- to 18-year-old Norwegian children, 38.9% of girls and 46.6% of boys reported lower extremity pain during the 3 months prior to survey, while 13.9% of girls and 18.4% of boys reported arm pain. In a 9-year, 6-point, longitudinal survey, British researchers found that 56.6% of caregivers of 5- to 13-year-olds reported that their child often experienced extremity pain at the time of at least 1 survey. Over the 9-year course of the study, caregivers reporting extremity pain in their child increased from 15.1% for 5-year-olds to 32.5% for 13-year-olds. There is some evidence that extremity pain is more common in obese children than in controls. Overall, approximately 6% of pediatric office visits are related to extremity pain. Fortunately, most of these visits involve pain caused by minor trauma, overuse syndromes, and normal skeletal growth variants. Occasionally, however, limb pain is the presenting complaint of a systemic illness, a neoplasm, an infectious process, a nutritional derangement, a specific orthopedic disorder, or a rheumatologic disease. The challenge for the physician is to determine when the pain is significant without exposing the child to excessive diagnostic studies and without delaying treatment or referral. For the most part, this determination is based on the history and physical examination alone.

### EVALUATION

#### History

A thorough history from patients and parents often reveals the cause of extremity pain in children. Pain described as aching or cramping is likely to be muscular in origin. Bone pain is often described as deep and nerve pain as burning, tingling, or numbness. Referred pain is common in children; thus, although usually helpful, the location of pain may be deceiving. Migrating extremity pain is less likely to occur after

trauma and is more typical of systemic illnesses such as leukemia, acute rheumatic fever, disseminated gonorrhea, and arthralgia or arthritis associated with inflammatory bowel disease. The mode of onset, variability, duration, and frequency of pain also help in determining its cause. Activities associated with worsening or relief of pain can also lead to a diagnosis. Similarly, color change associated with extremity pain may indicate inflammation (faint red), infection (intense red), or autonomic dysfunction (pallor, cyanosis, and erythema). Stiffness, especially with clinical evidence of arthritis not associated with trauma, should prompt concern about a rheumatologic process.

A history specific to trauma associated with extremity pain can be helpful. Trauma accompanied by an audible pop or snap is more likely the result of a dislocation, sprain, or fracture. Mild trauma that leads to a fracture might indicate some previous defect in the bone, as with a pathological fracture. If the physical findings of trauma are greater than would be expected from the history, then physical abuse must be considered.

The child's general health history completes the picture of extremity pain. For example, the differential diagnosis changes with age. Toxic synovitis of the hip is a common diagnosis in a child younger than 10 years; a slipped capital femoral epiphysis is more likely in an overweight adolescent.

As a screen for systemic disease, all systems should be reviewed briefly. Particular attention should be paid to a history of fever, recent weight loss, sweating, rashes, and gastrointestinal symptoms. A history of recent medications is important and might reveal a serum sickness–like illness. Even a short course of systemic steroids can cause aseptic necrosis of the hip or can result in demineralization of bone. Immunizations, particularly for rubella, may cause joint or extremity pain, and a history of exposure to viral illness might explain myalgia or arthralgia. Specifically, both parvovirus and hepatitis B can cause significant arthralgia.

The patient's family history may reveal a tendency toward autoimmune disease or recent exposure to infectious diseases. The family history is particularly helpful in identifying hemoglobinopathies. A family history of sickle cell anemia in a 6- to 24-month-old child whose hands and feet are painfully swollen may lead to the diagnosis of hand-foot syndrome and previously undiagnosed sickle cell disease. A sickle cell pain crisis must always be considered in a black child or a child of Mediterranean origin who has a painful extremity. Human leukocyte antigen B27 is associated with reactive arthritis (formerly called Reiter syndrome), psoriatic arthritis, inflammatory bowel disease, and ankylosing spondylitis, and has been described in association with enthesitis-related arthritis (inflammation of tendons, ligaments, or fascia at their attachments to bone). Joint hypermobility syndrome and fibromyalgia also can be familial.

Extremity pain may be a symptom of a functional disorder and can serve as an entry to the physician's office. One large group of pediatric rheumatologists has estimated that 11% of their new patients suffer from psychosomatic musculoskeletal pain. In cases of

functional pain, the history may be either quite dramatic or highly understated. Pain in a nonanatomic distribution or that disturbs only unpleasant activities (waxing on school days and waning on weekends) should raise suspicion of a functional disorder. Eliciting a history of recent events at home, recent school performance, and other social history can be essential to determining the diagnosis.

### Physical Examination

A brief general physical examination is worthwhile even if the history points to extremity pain from minor local trauma. Abnormalities in blood pressure, heart rate, or growth pattern can reveal an endocrine cause. An elevated resting heart rate is associated with rheumatic fever. Pallor, fever, lymphadenopathy, or organomegaly may be clues to systemic disease. A rash may be particularly helpful. Dermatomyositis occurs with muscle pain and proximal weakness associated with a vasculitic rash on the extensor surfaces of knuckles, knees, and elbows (Gottron papules). Palpable purpura and extremity pain are associated with Henoch-Schönlein purpura. A photosensitive rash in a child who has limb pain might point to systemic lupus erythematosus, dermatomyositis, or parvovirus infection. Nail pitting is associated with psoriasis.

In a child with unexplained extremity pain, a thorough eye examination by an ophthalmologist may detect uveitis, sometimes associated with juvenile idiopathic arthritis. Photophobia, eye injection, or pain with accommodation associated with extremity pain warrants a consultation with a rheumatologist and ophthalmologist. A complete physical examination can reveal generalized joint laxity and hyperextensibility, differentiating benign hypermobility syndrome from a focal ligament injury. In benign hypermobility syndrome (Ehlers-Danlos syndrome type III), the joint laxity allows chronic hyperextension, which can cause pain, typically in weight-bearing joints. The pain often is worse in the evening. Dancing and gymnastics may exacerbate arthralgia, as can any other joint-impacting activity.

Claudication is a rare cause of extremity pain in children. However, in popliteal artery entrapment syndrome, vascular calf pain that radiates to the foot is associated with an anomalous popliteal artery or anomalous placement of the gastrocnemius muscle. The pain begins with activity, sometimes more with walking than with running. This syndrome is suggested if normal pedal pulses are lost with simultaneous knee extension and foot plantar flexion.

Because referred pain is common in children, the physical examination should include areas proximal and distal to the site of the complaint. A slipped capital femoral epiphysis and Legg-Calvé-Perthes disease, both of which affect the hip, can produce knee or thigh pain, whereas an abscess of the psoas muscle may cause hip pain. Appendicitis and other intra-abdominal processes and diskitis can also cause pain that is referred to a lower extremity.

Examination of a painful extremity should include assessment of peripheral vascular status, muscle strength, soft-tissue swelling, and skeletal injury.

Disruption of joint integrity may be shown by demonstration of abnormal range of motion of the joint with passive movement. Peripheral vascular status is assessed by palpating the pulses and determining the capillary refill time distal to the pain. Skin color and warmth, tenderness to palpation, and the extent of passive and active range of motion should all be assessed. Swelling, warmth, and erythema over a joint are signs of arthritis. Point tenderness over a bone raises suspicion of a fracture. Point tenderness in the absence of a clear history of trauma may indicate osteomyelitis. Comparing the opposite limb is helpful when assessing swelling, muscle wasting, or joint mobility. Observing the patient's gait or use of the painful limb when the patient is unaware of the observation helps in diagnosing a functional process. Isolated distal weakness is likely to be of neurologic origin, whereas proximal weakness is most likely from muscular disease. Finally, with chronic extremity pain, serial examinations of the patient over the course of weeks can be the key to diagnosis.

### Laboratory Examination

Laboratory studies are unnecessary for most extremity pain. However, if the history and physical examination do not lead to a definitive diagnosis, if they raise suspicion of a systemic or an infectious disease, or if the pain persists longer than anticipated, then screening laboratory tests are in order. A basic evaluation should include a complete blood cell count (CBC), a sedimentation rate, a C-reactive protein, and a sickle cell preparation or hemoglobin electrophoresis when indicated. Appropriate serologies should be considered if features of the physical examination are consistent with rheumatologic disease. An elevated sedimentation rate raises suspicion of an infectious or inflammatory disorder or, occasionally, of a neoplasm. A CBC may reveal anemia or may suggest an infectious disease. With leukemia, the white blood cell (WBC) count varies, but immature forms may be present in the differential WBC count or thrombocytopenia may be present. A creatine phosphokinase determination is occasionally indicated if muscular pain or weakness is suspected.

### Imaging

Radiologic studies are often unnecessary in evaluating limb pain. However, because of the plasticity of children's bones, traumatic injury that would ordinarily cause only a sprain in an adult is more likely to result in a greenstick or buckle fracture in a child. The presence of point tenderness or gross deformity in an extremity or pain on motion of the involved limb increases the likelihood of fracture. In an effort to minimize the use of radiographic studies after traumatic injury to the knee and ankle, The Ottawa Criteria have been developed for use in adults. These criteria have also now been validated for use in children older than 5 years (Box 147-1). When no clear history of trauma is revealed, when symptoms persist, and when associated systemic complaints are present, radiographs can help identify bony tumors, pathological fractures, some metabolic defects, and a significant number of orthopedic conditions.

### BOX 147-1 Indication for Plain Radiograph Evaluation After Trauma Using the Ottawa Ankle and Knee Rules

Radiograph of the knee is indicated after trauma if<sup>a</sup>

- Age older than 55 years
- Isolated tenderness of patella
- Tenderness at the head of the fibula
- Inability to flex the knee to 90 degrees
- Inability to bear weight both immediately and at medical evaluation

Radiograph of the ankle is indicated after trauma in cases of<sup>b</sup>

- Pain in the malleolar zone and (1) tenderness of the tip of the medial malleolus or bone tenderness of the distal 6 cm of posterior tibia, OR (2) tenderness of the tip of the lateral malleolus or bone tenderness of the distal 6 cm of the posterior fibula, OR (3) inability to bear weight immediately after injury and at the time of medical evaluation.

Radiograph of the foot is indicated after trauma in cases of

- Pain in the midfoot zone and (1) tenderness at the base of the fifth metatarsal, OR (2) tenderness at the navicular bone, OR (3) inability to bear weight immediately after injury and at the time of medical evaluation.

<sup>a</sup>Dowling S, Spooner CH, Liang Y, et al. Accuracy of Ottawa Ankle Rules to exclude fractures of the ankle and midfoot in children: a meta-analysis. *Acad Emerg Med.* 2009;16(4):277–287

<sup>b</sup>Vijayasankar D, Boyle AA, Atkinson P. Can the Ottawa knee rule be applied to children? A systematic review and meta-analysis of observational studies. *Emerg Med J.* 2009;26(3):250–253

A bone scan is a useful diagnostic tool in evaluating limb pain and should be considered when a stress fracture, osteomyelitis, or malignancy is suspected. Bone scans are more sensitive than plain-film radiography for establishing these diagnoses. Increasingly, magnetic resonance imaging (MRI) is being used as a replacement for bone scans in the diagnosis of osteomyelitis. The combined use of T1, T2, and short-tau inversion-recovery images effectively rules out osteomyelitis, with a negative predictive value approaching 100%. MRI offers the additional advantage of excellent visualization of soft-tissue and joint disease. There may still be a role for bone scan in the evaluation for osteomyelitis when need for sedation is a concern and when the area of potential involvement cannot be adequately narrowed based on physical examination.

### Differential Diagnosis

The differential diagnosis of extremity pain is extremely broad (Box 147-2). However, most limb pain is benign, requires no intervention, and is self-limited. Characteristic patterns of pain and associated signs and symptoms signal the presence of certain diseases and conditions. A discussion of some of these disorders follows.

### Growing Pains

Growing pains are a time-honored pediatric disorder. They are intermittent, deep extremity pains that affect the lower more often than the upper extremities. The pain is nearly always bilateral, rarely involves the joints, and is almost universally worse at night, lasts fewer than 2 hours, and resolves completely in the morning. Despite their name, growing pains do not

### BOX 147-2 Extremity Pain in Childhood: Differential Diagnosis

#### IMMUNE-MEDIATED ORIGIN

- Dermatomyositis
- Familial Mediterranean fever
- Guillain-Barré syndrome
- Henoch-Schönlein purpura
- Inflammatory bowel disease
- Juvenile idiopathic arthritis
- Kawasaki disease
- Mixed connective-tissue disease
- Polyarteritis nodosa
- Rheumatic fever
- Scleroderma
- Serum sickness
- Systemic lupus erythematosus

#### CONGENITAL ORIGIN

- Caffey disease
- Hemophilia
- Hypermobility syndrome (Ehlers-Danlos syndrome type III)

- Mucopolidosis
- Mucopolysaccharidosis
- Osteogenesis imperfecta
- Popliteal artery entrapment syndrome
- Sickle cell anemia, thalassemia

#### ENDOCRINE ORIGIN

- Hypercortisolism
- Hyperparathyroidism
- Hypothyroidism

#### IDIOPATHIC ORIGIN

- Fibromyalgia
- Growing pains
- Restless leg syndrome
- Sarcoidosis

#### INFECTIOUS ORIGIN

##### *Bacterial*

- Arthralgia or myalgia associated with streptococcal infection
- Diskitis, spinal epidural abscess

*Continued*

**BOX 147-2 Extremity Pain in Childhood: Differential Diagnosis—cont'd**

- Gonorrhea
- Osteomyelitis
- Pyogenic myositis
- Septic arthritis
- Enteric disease
- Meningococcal disease
- Syphilis: periostitis
- Tuberculosis

**Viral**

- Myalgia, arthralgia
- Myositis
- Toxic synovitis

**Other**

- Histoplasmosis
- Immunization reaction
- Trichinosis

**METABOLIC ORIGIN**

- Carnitine palmityltransferase deficiency
- Fabry disease
- McArdle syndrome
- Phosphofructokinase deficiency

**NEOPLASTIC ORIGIN**

- Langerhans cell histiocytosis
- Leukemia
- Lymphoma
- Neuroblastoma
  - Chondrosarcoma
  - Ewing sarcoma
  - Osteoblastoma (benign)
  - Osteogenic sarcoma
  - Osteoid osteoma (benign)
- Tumors of soft tissue
  - Fibrosarcoma
  - Rhabdomyosarcoma
  - Synovial cell sarcoma
- Tumors of the spinal cord
- Tumors of bone

**NUTRITIONAL ORIGIN**

- Gout
- Hypercholesterolemia

- Hypervitaminosis A
- Osteoporosis
- Rickets (vitamin D deficiency)
- Scurvy (vitamin C deficiency)

**ORTHOPEDIC ORIGIN**

- Chondromalacia patellae
- Freiberg disease
- Inflexible flat feet, tarsal coalition
- Kohler disease
- Legg-Calvé-Perthes disease
- Osgood-Schlatter disease
- Osteochondritis dissecans
- Osteogenesis imperfecta
- Pathological fracture
- Sever disease
- Slipped capital femoral epiphysis

**PSYCHOSOCIAL ORIGIN**

- Behavior disorders
- Psychogenic pain
- Reflex neurovascular dystrophy
- School phobia

**TRAUMA OR OVERUSE**

- Compartment syndrome
- Fracture
- Myohematoma
- Myositis ossificans
- Nerve compression syndrome
  - Carpal tunnel syndrome
  - Cervical nerve root entrapment
- Other peripheral nerve root compression
- Physical abuse
- Shin splint
- Sprain
- Stress fracture
- Subluxed radial head
- Thoracic outlet syndrome

occur most frequently during periods of rapid growth. Instead, their onset is described at 3 to 5 or 8 to 12 years of age. For many children growing pains resolve in 12 to 24 months; however, they may persist into adolescence. In a 5-year follow-up of 35 children with growing pains, half had resolution of the condition and nearly all had improvement.

The cause of growing pains remains unclear. However, headache and abdominal pain, often associated with emotional illnesses, also have accompanied

growing pains. In the 5-year follow-up study, only children with persistent growing pains had lower pain thresholds than controls.

The diagnosis of growing pains is significant for its lack of associated physical signs. Thus, any abnormal finding on physical examination should provoke a search for another cause. Similarly, radiographs and the results of screening laboratory tests usually prove normal. Treatment involves heat, massage, and analgesics.

## Sprains

A sprain is a physical disruption of a ligament. In children, sprains occur less commonly than in adults because a child's open epiphyseal plate or plastic bony cortex tends to give way more easily than does a ligament. Therefore, Salter-Harris fractures and buckle fractures should be considered when the history indicates a sprain and when physical examination reveals tenderness on palpation or pain on stretching the ligament. Joint stability should also be assessed. Sprains can be graded according to the degree of associated ligament disruption. A mild, microscopic tear that results in no laxity of the involved joint is a grade I sprain. Grade II sprains involve macroscopic but incomplete ligament tears. Joint laxity is greater, but less than a 5-mm movement differential exists between the sprained and the contralateral joint. Grade III sprains result in more than 5 mm of increased mobility of the affected joint. The primary care physician can treat grade I sprains by icing and wrapping the involved joint to minimize swelling. Early range of motion exercises should be encouraged, with a gradual return to activity. The recurrence of pain indicates too rapid a return to a given level of activity. Grade II and grade III sprains should generally be referred to an orthopedist or sports medicine physician for immobilization and consideration of surgical repair of torn ligaments.

## Overuse Syndromes

Overuse injuries have become more common as organized sports for children have become popular nationwide and as the competitive level of some sports activities has increased. Localized, gradually increasing, and persistent extremity pain that worsens with weight bearing, exercise, and activity, but that diminishes with rest, can indicate a stress fracture. Stress fractures are rare in children younger than 12 years. They most commonly affect the second metatarsal, the proximal tibia, or the fibula. A radiograph may show normal findings, and although a bone scan or an MRI can help establish the diagnosis they are not routinely indicated because treatment consists mostly of rest and nonsteroidal anti-inflammatory agents. Casting or splinting is occasionally necessary.

*Little League elbow* is an overuse injury caused by the repetitive motion of pitching a baseball; this motion compresses the radial aspect of the elbow and stretches the ulnar aspect. The result is painful inflammation of the epicondyles. The range of joint motion also may be diminished. Fragments of bone splintered into the joint may cause the joint to catch or lock. Treatment consists of resting the arm by avoiding the repetitive movement. A change in pitching technique may reduce recurrences. To prevent this problem, some Little League systems limit both the number of innings a child may pitch in a game and the age at which certain pitches can be thrown.

Shin splints are also caused by overuse. The term originally referred to pain along the posteromedial aspect of the tibia as a result of irritation at the origin of the posterior tibial muscle. Shin splints now refer to any of a series of painful overuse syndromes of the lower portion of the leg, including irritation of the

posterior or anterior tibial muscle, inflammation of the interosseous membrane located between the tibia and fibula, and both anterior and posterior compartment syndromes. All of these abnormalities can cause pain in the lower legs. The condition, which is exacerbated by running and jumping, occurs most commonly at the beginning of a training season. Although the pain occurs initially after activity, it may occur during or before activity as the syndrome progresses. On examination, tenderness may be felt over the posteromedial aspect of the tibia, over the proximal portion of the posterior tibia, or over the anterior tibia. Differential diagnosis includes Osgood-Schlatter disease with pain localized to the tibial tuberosity. Treatment of shin splints involves rest, application of ice, and anti-inflammatory agents. For runners, training on a softer surface or with better-quality running shoes may help.

## Subluxation of the Radial Head

Nursemaid's elbow is a common injury in toddlers. The injury usually follows sudden, forceful traction of the hand or forearm, which pulls the immature radial head briefly from the cuff formed by the annular ligament. Release of the force allows the radius to trap the ligament against the capitellum. A verbal patient usually localizes the pain to the elbow or, occasionally, to the wrist. More often, the child refuses to use the extremity and holds the arm with the elbow flexed, the forearm close to the chest, and the hand in pronation. The diagnosis is usually made by history alone. If the history is unclear, or if attempts to reduce the subluxation are unsuccessful, then radiographs may be obtained to rule out a fracture. Radiographic findings in subluxation of the radial head usually are negative. The physician can reduce the subluxation by using 1 hand to supinate the patient's forearm quickly while simultaneously exerting traction on the forearm and using the thumb of the other hand to create pressure over the patient's radial head. This maneuver is completed by placing the elbow through full extension and flexion while maintaining pressure over the radial head. Alternatively, the child's forearm can be fully pronated instead of supinated, and then either fully extended or flexed. With either maneuver, normal use of the extremity usually returns within 30 minutes. The rapid recovery is dramatic and rewarding to the parents and the physician. A prompt return to normal use of the affected arm may not occur if the subluxation has been present for some time because of swelling of the ligament. In such instances, the affected arm should be placed in a simple sling and positioned across the upper portion of the abdomen for 12 to 24 hours. Referral to an orthopedist is rarely required.

## Slipped Capital Femoral Epiphysis

A slipped capital femoral epiphysis is caused by a sudden or gradual dislocation of the head of the femur from its neck and shaft at the level of the upper epiphyseal plate. The characteristic pain occurs in the affected hip or the medial aspect of the ipsilateral knee. The displacement may be sudden, in which case the pain is usually severe and associated with the inability to bear weight. Gradual displacement is associated with slowly increasing, dull pain. This condition

typically affects sedentary, obese adolescent boys. The physical examination may reveal diminished abduction and internal rotation of the hip. The diagnosis is made radiographically. Management involves surgical placement of a pin through the femoral head and the epiphysis to prevent further slippage. Avascular necrosis of the femoral head is a common complication, even with early recognition and treatment.

### Toxic Synovitis

Toxic synovitis, a self-limited inflammation of the hip joint, commonly occurs in children younger than age 10 years. The cause is unknown; however, because it often occurs within 2 weeks after an upper respiratory infection, a postviral inflammatory process is suspected. Typical presentation is that of a child who refuses to walk because of apparent pain in the hip. The hip is held in flexion, abduction, and external rotation. Findings may include a slight elevation in the WBC count and the sedimentation rate, a frustrating development for the physician, who hopes to rule out septic arthritis. A C-reactive protein of less than 1 mg/dL has been shown to have an 87% negative predictive value for septic arthritis. This study may offer reassurance. However, persistent concern for septic arthritis may lead to consultation with an orthopedist. Treatment of toxic synovitis consists of bed rest, usually for fewer than 4 days. In rare instances, avascular necrosis of the femoral head may be a late complication.

### Osteochondroses

Osteochondroses include a group of disorders in which degeneration or aseptic necrosis of bone and overlying cartilage occurs at an ossification center and is followed by recalcification. The disorders vary in name and presentation according to their locations.

Legg-Calvé-Perthes disease, or osteochondrosis of the femoral head, results from compromise of the tenuous vascular supply to the area. The condition may be idiopathic or may result from a slipped capital femoral epiphysis, trauma, steroid use, sickle cell crisis, or congenital dislocation of the hip. Toxic synovitis also is associated with subsequent Legg-Calvé-Perthes disease, but not commonly. After compromise of the vascular supply, the bone underlying the articular surface of the head of the femur becomes necrotic. Collapse of the necrotic bone flattens the femoral head and causes a poor fit with the acetabulum, even after new bone is formed. The pain associated with Legg-Calvé-Perthes disease, which results from necrosis of the involved bone, is often referred to the medial aspect of the ipsilateral knee. A limp may be the presenting complaint. In many instances, an early diagnosis eludes the physician because radiographic findings may be normal or show only swelling of the joint's capsule. A bone scan may demonstrate diminished blood flow to the femoral head compared with the contralateral hip. Later, radiographs may show areas of bone resorption, irregular widening of the epiphysis, or dense new bone formation. The goal of therapy is to prevent flattening of the femoral head as it undergoes new bone formation by keeping the hip abducted so that the head of the femur is held well inside the rounded portion of the acetabulum. Either bracing or

an osteotomy may accomplish this task; both require referral to an orthopedic surgeon.

Two similar processes can affect the knee joint. Osteochondritis dissecans involves degeneration of bone and cartilage at the articular surface of the knee, particularly at the lateral aspect of the medial condyle of the femur. Knee pain, crepitus, or a sensation of instability or locking caused by loose bone and cartilage fragments in the joint can result. Chondromalacia patellae occurs because of a painful softening or breakdown of the inner surface of the patella. The pain is localized to the knee and increases with activities that require prolonged knee bending and even with prolonged sitting. The pain is described as grinding and can sometimes be elicited by applying pressure over the patella. Moving the patella from side to side over the knee joint may cause crepitus and apprehension. Treatment is usually limited to pain relief and reassurance that, in time, the condition will resolve. Exercise to strengthen the medial quadriceps muscles and to stretch the hamstrings may promote better alignment of the patella with the knee and thereby diminish the pain. Rarely, in severe cases, the patella may have to be realigned surgically. Osteochondrosis of the growth plate of the calcaneus (Sever disease) can produce heel pain that worsens with activity. This usually mild process requires only rest, nonsteroidal anti-inflammatory agents, and padding of the heel to relieve the pain. Avascular necrosis and osteochondrosis of the tarsal navicular bone (Kohler disease) and of the head of the second metatarsal (Freiberg disease) can cause foot pain. Treatment usually requires only pain medication and rest.

Osgood-Schlatter disease is a painful degeneration of the tibial tubercle at the site of insertion of the quadriceps ligament. It is characterized by painful swelling of the anterior aspect of the tibial tubercle, usually occurring during adolescence. The degree of swelling may be alarming, and the area is tender to palpation. Pain is exacerbated by activity that involves increased use of the quadriceps muscles. The process is self-limited and resolves toward the end of adolescence when the epiphysis at the insertion site closes and the bone becomes stronger than the inserted ligament. Until it resolves, the condition is treated with rest, analgesics, and, occasionally, supportive patellar knee straps. In rare cases, casting or surgical attachment of the quadriceps ligament is required.

### Osteomyelitis

Osteomyelitis is a local infection of bone, usually involving 1 of the long bones. The highest incidence is in children 3 to 12 years of age. Although infection often occurs by hematogenous seeding, it can be caused by direct entry after local trauma. In both children and adults, the most commonly isolated organism is *Staphylococcus aureus*. Improved diagnostic testing has allowed identification of *Kingella kingae* as 1 of the primary pathogens of osteomyelitis (and septic arthritis) in children younger than 6 years. Effective vaccination for *Haemophilus influenzae* type b has made this pathogen a rare cause of osteomyelitis in immunized children. Other organisms, including *Salmonella* species and group A streptococci also infect the bone.

Group B *Streptococcus* is more likely the cause of infection in newborns. Osteomyelitis caused by *Salmonella* tends to occur more often in children who have sickle cell anemia than in other children. In assessing trauma from a puncture wound to the foot, especially through a sneaker, *Pseudomonas aeruginosa* must be considered. In addition, tuberculous osteomyelitis still occurs and may become more common with the resurgence of tuberculosis.

Osteomyelitis can produce extremity pain alone or extremity pain with signs of a systemic infectious disease (fever, irritability, septic appearance). In the absence of systemic signs, distinguishing between osteomyelitis and a traumatic cause of the pain is often difficult. A period of 2 weeks or longer may be required for radiographic evidence of osteomyelitis to develop. A bone scan is usually, but not always, diagnostic. In rare cases, a reduction in perfusion caused by pressure from the exudative process may result in false-negative scans. MRI is now the preferred test for confirming this diagnosis. In addition, the WBC count and sedimentation rate are often elevated in osteomyelitis. The effectiveness of treatment can be monitored by repeating tests of the sedimentation rate or the C-reactive protein.

### Neoplasms

Although neoplasm is not commonly the cause of limb pain, the possibility of a tumor is a common concern for parents of children who have this complaint. Even if rare, benign and malignant bone tumors and systemic malignancies can cause limb pain.

Osteoid osteoma is a benign prostaglandin-secreting bone tumor that occurs most often in adolescents and usually involves a femur, tibia, or lumbar vertebral body. Pain, the presenting complaint, is initially dull and increases in intensity to deep and boring. The pain is more intense at night and with weight bearing. Radiographic findings of sclerotic bone around a lucent center are diagnostic of this condition; tomograms are sometimes required for confirmation. Surgical excision is curative.

Systemic neoplasms in which extremity pain occurs include leukemia and metastatic neuroblastoma. Childhood leukemia is an uncommon cause of extremity pain. However, up to one-third of children who have acute lymphocytic leukemia have bone pain at the time of diagnosis, and in one-fourth of children, joint or bone pain is a significant presenting complaint. Unrelenting, increasing pain that worsens at night or with rest and that is not relieved by analgesics, heat, or massage may indicate the presence of a metastatic bone tumor. Systemic signs (weight loss, pallor, lymphadenopathy, hepatosplenomegaly, or fever) may accompany the pain. In leukemia, examination of the extremity may reveal strikingly little to account for the degree of pain. Radiographic studies of the extremities may show lucent leukemic lines in the subepiphyseal area.

Primary malignant tumors of bone may cause severe unilateral pain, with swelling and tenderness at the tumor site. The possibility of this diagnosis supports the use of radiographic studies when unilateral limb pain is not explained adequately by a

history of trauma and when pain from trauma does not resolve as expected. The peak incidence of both osteogenic sarcoma and the less common Ewing sarcoma occurs in late childhood and during adolescence. The radiograph of an osteogenic sarcoma may reveal a tumor in the metaphysis with the presence of both radiolucent and radiopaque areas. The characteristic sunburst results from extension of calcification into the overlying soft tissue. Although periosteal elevation may be present, it is not diagnostic of the disease.

### WHEN TO REFER

- Surgical procedure or subspecialist required for definitive treatment (eg, suspected anterior cruciate ligament tear, Ewing sarcoma, other associated conditions)
- Surgical procedure or subspecialist required for diagnostic evaluation (eg, suspected septic arthritis, juvenile idiopathic arthritis, systemic lupus erythematosus, other associated conditions)
- Extremity pain part of multisystemic signs and symptoms (eg, Fabry disease, Crohn disease, other associated conditions)

## Chapter 148

# FACIAL DYSMORPHISM

Robert W. Marion, MD; Joy Samanich, MD

*"It is my business to know things. Perhaps I have trained myself to see what others overlook."*

SHERLOCK HOLMES, "A CASE OF IDENTITY"

If someone were searching for a role model for the field of dysmorphology, the study of the recognition of patterns of congenital malformations and dysmorphic features that characterize particular syndromes, Sir Arthur Conan Doyle's famous detective, Sherlock Holmes, would be an excellent candidate. Like Holmes, the dysmorphologist, who is a subspecialist within the field of medical genetics, searches for clues when evaluating a patient: sometimes facts become available from a carefully obtained history; sometimes facial features that are in plain sight can lead to a diagnosis; and, similar to a detective solving a crime, the dysmorphologist attempts to assemble these bits of information into a single, unifying diagnosis. These clues may be obvious, or they may be so subtle that other physicians simply overlook them. Their diagnostic significance and the information they may provide about the developmental timing of a congenital anomaly, however, may prove invaluable.

## DEFINITIONS

Defined as clinically significant abnormalities in form or function, congenital *malformations* result from localized, *intrinsic* defects in morphogenesis that occur in embryonic or early fetal life. These defects, which include clefting of the lip or palate, congenital heart disease such as tetralogy of Fallot, and multicystic kidney disease, may result from an unknown cause, but increasingly can be traced to mutations in or deletions of single developmental genes. Malformations usually require surgical intervention.

*Deformations* differ from malformations in that they arise from environmental forces acting on *normal tissue primordia*. For example, a fetus reared in a uterus in which a large fibroid is present may have limited space for the limbs to go through their normal range of motion; limitation of motion of the limbs leads to congenital contractures, a condition known as *arthrogryposis multiplex congenita*. Deformations occur later than malformations, usually after the first trimester of pregnancy is completed, and they often resolve with minimal therapy.

A malformation such as a cleft lip or cleft palate or a deformation such as clubfoot deformity (Figure 148-1) may occur as an isolated feature or, in instances in which multiple malformations occur together, may be part of a *malformation sequence*, a *syndrome*, or an *association*.

When a single malformation causes secondary effects on other structures later in development, a

malformation sequence will result. For instance, in the Pierre Robin malformation sequence, the primary malformation, failure of the growth of the mandible during the first weeks of gestation, results in micrognathia (small jaw); because of the insufficient size of the jaw, the tongue, which is normal in size, is forced into an unusual position; the abnormally placed tongue blocks the fusion of the palatal shelves that normally come together in the midline, thus producing a U-shaped cleft of the palate; after delivery, the normal-sized tongue in the smaller-than-normal oral cavity leads to airway obstruction and obstructive apnea, a potentially life-threatening complication. Thus, 3 anomalies result from the single malformation.

In clinical genetics, a syndrome is defined as a group of malformations that occur together and are caused by a clearly identifiable causative agent. This agent may be a single gene mutation; such is the case in Marfan syndrome in which a mutation in the *FBN1* gene on chromosome 15 leads to abnormally formed fibrillin, an important component of the myofibrillar array of connective tissue. The result is a characteristic set of abnormalities of the skeletal, cardiovascular, and ophthalmologic systems. Single gene mutations account for approximately 7.5% of all multiple malformation syndromes. A second cause of a syndrome can be a chromosomal abnormality, as in Down syndrome, in which an extra copy of chromosome 21 leads to craniofacial dysmorphic features, developmental disabilities, cardiac anomalies, and other abnormalities. Approximately 6% of infants with multiple malformation syndromes have a chromosomal abnormality. A third underlying cause of a syndrome can be a teratogenic agent—a drug, chemical, or environmental toxin that causes damage to the developing embryo or fetus. One example is valproic acid, an anticonvulsant that when given to a woman during the first trimester of pregnancy leads to spina bifida, a characteristic facial appearance, limb defects, and other anomalies in exposed embryos. Teratogens account

**Figure 148-1** Club feet. (From Hoyme HE. Assessing dysmorphology in primary care. In: Saul RA, ed. Medical Genetics in Pediatric Practice. Elk Grove Village, IL: American Academy of Pediatrics; 2013:135–174.)

for approximately 6% of cases of infants with multiple malformation syndromes. Finally, a syndrome can result from unknown factors, as is the case with septo-optic dysplasia, which is characterized by midline brain abnormalities, optic nerve hypoplasia and pituitary endocrine dysfunction. Though a small number of patients (<1%) with septo-optic dysplasia have a mutation in the *HESX1* gene, most individuals with this condition have no identifiable underlying cause.

Associations differ from syndromes in that no single underlying cause has been identified to explain a recognizable pattern of anomalies that occur together more than would be expected by chance alone. One example is the VACTERL association (vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies, and limb anomalies). Because no single unifying cause that explains this condition has been identified, it is considered an association. When the cause of an association becomes known, the disorder is recategorized as a syndrome. This change recently happened with the CHARGE association (coloboma, heart disease, atresia choanae, retardation of growth or development, genitourinary tract anomalies, and ear anomalies) when, in 2004, this entity was found to be related to mutations in the *CHD7* gene on chromosome 8. Identification of mutations in this gene in patients with this condition allowed CHARGE association to become CHARGE syndrome.

Between 2% and 5% of newborns are found during the neonatal period to have 1 or more congenital malformations. This percentage increases at 1 year of age to between 7% and 8% because some malformations, such as congenital heart disease and renal anomalies, may remain clinically silent during the newborn period only to display later in life. In approximately one-half of children with congenital malformations, only a single malformation is identifiable; in the other half, multiple malformations are present.

## APPROACH TO THE CHILD WITH DYSMORPHIC FEATURES

The birth of a child with dysmorphic features is a difficult and unsettling experience for the family, the

physician, and the medical staff. In many instances, recognition of any problem in an infant will lead to a crisis for the family; the physician caring for the infant and the family may easily panic in such a situation. Therefore, establishing a standardized routine in a format that can routinely be followed when the physician is faced with such a situation is helpful for the evaluation of the child with dysmorphic features. This routine should include taking the history, including a 3-generational family history, and performing a careful physical examination. Following these steps, specific diagnostic laboratory tests can be ordered to confirm a diagnosis (Box 148-1).

When approaching a child with dysmorphic features, physicians must be sensitive about the terminology used to describe the infant. The terms *funny-looking kid* and *funny-looking face* are derogatory, justifiably arouse parental indignation, and should be avoided at all times. In discussing dysmorphic features with parents or describing them in written or verbal communication with colleagues, the physician should describe the abnormal features as clearly and concisely as possible.

### History

In taking the history, the following questions about the pregnancy should be asked:

1. *What was the birth weight?* A lower-than-expected birth weight can be associated with a chromosomal anomaly or exposure to a teratogen. Babies who are large for gestational age may be infants of diabetic mothers or have an overgrowth syndrome, such as Beckwith-Wiedemann syndrome. Infants who are accurate for gestational age may have a single gene mutation, a multifactorial condition, or, most likely, no genetic disease at all.
2. *Was the baby full term, premature, or postmature?* This information is especially important when evaluating an older child with developmental disabilities. Complications of extreme prematurity may be responsible for the patient's problems. Postmaturity is associated with some chromosome anomalies (such as trisomy 18) and anencephaly.
3. *Was the baby born by vaginal or cesarean delivery? If the latter, what was the indication?* These questions are helpful in evaluating the newborn with dysmorphic features and in older children with developmental disabilities. Cesarean delivery may be performed because of fetal distress, a risk factor for developmental disability caused by oxygen deprivation. Furthermore, babies born from breech presentation are approximately 4 times more likely than infants born from vertex presentation to have congenital malformations.
4. *How old were the parents at the time of the child's delivery?* Advanced maternal age is associated with an increased risk of nondisjunction leading to trisomies, such as Down syndrome (trisomy 21), whereas advanced paternal age may be associated with an increased risk of a new mutation leading to an autosomal dominant trait, such as achondroplasia.
5. *Did the pregnancy have complications? Does the mother have underlying medical problems? Does*

### BOX 148-1 Evaluation of the Individual Who Has Facial Dysmorphism

- Review the pregnancy and medical history.
- Review the family history.
- Evaluate growth of the individual in height, weight, and head circumference.
- Evaluate the craniofacial region for dysmorphic features, and describe any such features that are found.
- Describe any other dysmorphic somatic features.
- Define the development of the individual.
- Develop a differential diagnosis and consider appropriate laboratory tests.
- Discuss the findings with the family and, if appropriate, offer genetic counseling.

she take any medications? Did she smoke cigarettes, drink alcohol, or take any drugs? Exposure of the embryo to teratogens—medications, or environmental agents known to cause birth defects—is a significant cause of congenital malformations.

6. *When did the mother feel quickening? Were fetal movements active?* Quickening, which normally occurs between 16 and 20 weeks' gestation, is delayed in hypotonic fetuses, who also have movements during fetal life that are not as vigorous as those of a fetus with normal muscle tone. Additionally, a mother's report of persistent hiccups in an infant found to have neonatal seizures suggests a prenatal onset of the condition.
7. *Was the amount of amniotic fluid normal?* An increased amount of amniotic fluid is associated with intestinal obstruction or a central nervous system anomaly that leads to poor swallowing, whereas a decreased amount of fluid may point to a renal or urinary tract abnormality that leads to failure to produce urine or a chronic amniotic fluid leak.

A 3-generation pedigree should be constructed, searching for similar and dissimilar abnormalities in first- and second-degree relatives; a history of pregnancy or neonatal losses should also be documented.

### Physical Examination

In the process of evaluating the child with dysmorphic features, the physical examination is the most important element. Whenever possible, the patient should be examined using a standardized approach, described in the following sections.

#### Growth

The height (length), weight, and head circumference should be carefully measured and plotted on appropriate growth curves. Growth that is appropriate for age may be consistent with the presence of a single gene disorder, a multifactorially inherited condition, or, most commonly, no genetic disease. Small size or growth restriction may be secondary to a chromosomal abnormality, a skeletal dysplasia such as achondroplasia, or exposure to toxic or teratogenic agents. Larger-than-expected size suggests an overgrowth syndrome (eg, Soto or Beckwith-Weidemann

syndromes) or, if in the newborn period, of maternal diabetes.

#### Proportions

Do the limbs look appropriate for the head and trunk? If not, then are the limbs too short (implying the presence of a short-limbed bone dysplasia such as achondroplasia)? A trunk and head that are too small for the extremities may suggest a disorder affecting the vertebrae, such as spondyloepiphyseal dysplasia.

#### Craniofacial Features

Careful examination of the craniofacies is crucial for the diagnosis of many congenital malformation syndromes. Often, a careful observer can make a diagnosis simply by looking at the child's face.

In assessing the face, head shape and facial features should be systematically observed.

**HEAD SHAPE.** In the newborn period, molding may cause the head to be misshapen, the result of a late prenatal deformational process (see previous discussion). The examiner will need to allow a few days for the deformation to resolve before assessing the shape. The head should then be described using the following terms:

- *Normocephaly* describes a normal head shape.
- *Dolichocephaly* or *scaphocephaly* describes a long, thin head.
- *Brachycephaly* describes a head that is narrow in the anteroposterior diameter and broad laterally.
- *Plagiocephaly* describes a head that is asymmetric or lopsided.

**FACIAL FEATURES.** A dysmorphic face may be appropriate in relation to the family's physiognomy, or it may indicate a particular syndrome. The child who has a large head who also has a parent with a large head does not prompt as much concern as the large-headed child whose parents have normal-size heads. Thus, the examiner must evaluate dysmorphic facial features in light of the child's genetic background. (Table 148-1 lists examples of genetic causes of facial malformation.)

In evaluating the face, the examiner should first note the symmetry. Facial asymmetry may result from a deformation related to intrauterine or extrauterine positioning or a malformation of 1 side of the face, as

**Table 148-1** Examples of Genetic Causes of Facial Malformation<sup>a</sup>

CAUSE	EXAMPLE	FACIAL DYSMORPHISM
Chromosomal	Down syndrome (trisomy 21)	Midface hypoplasia, upward obliquity of palpebral fissures, epicanthal folds, flat nasal bridge, anteversion of nares
Autosomal dominant	Treacher Collins syndrome	Dysplastic ears, maxillary hypoplasia
Autosomal recessive	Hurler syndrome	Corneal clouding, coarse facies
Teratogenic: intrauterine infection	Congenital rubella	Cataracts
Drug induced	Fetal alcohol syndrome	Smooth philtrum (Figure 148-2), small eyes

<sup>a</sup>Smith's *Recognizable Patterns of Human Malformation* is the most valuable resource for this purpose; it also is helpful in determining if a particular condition is genetically based.

is the case with *hemifacial microsomia* (also known as Goldenhar syndrome or *oculoauriculovertebral syndrome*).

For purposes of evaluation, the face should be divided into 4 regions, each of which should be evaluated separately.

1. The *forehead* extends from the anterior hairline to the eyebrows.
2. The *midface* encompasses the region from the eyebrows to the upper lip and laterally from the outer canthus of each eye to the outer commissure of the lips.
3. The *malar region* extends on either side from the upper portion of the ear to the midface.
4. The *mandible* extends from lower ear to lower ear and including the lower lip.

By analyzing each of these 4 regions and determining which is typical and which is not, a clear description of the child's dysmorphic features can be made.

The forehead may show overt prominence (as is the case with *achondroplasia*) or deficiency (often described as a *sloping* appearance, which occurs in children with primary microcephaly).

Hypoplasia of the midface is a common component of many syndromes, including Down syndrome and fetal alcohol syndrome. Evaluating the midface involves careful assessment, first by measurement and then through plotting those measurements on appropriate growth curves, of both the distance between the eyes

(inner and outer canthal distances) and pupils (interpupillary distance). Such assessment may confirm the impression of hypotelorism (eyes that are too close together), suggestive of a defect in midline brain formation (holoprosencephaly); or hypertelorism (eyes that are too far apart), suggestive of a syndrome such as *Opitz syndrome* (ocular hypertelorism, tracheal and esophageal anomalies, and hypospadias). The length of the palpebral fissure should be noted and plotted on the appropriate growth chart; palpebral fissures may be short in fetal alcohol syndrome or excessively long in Kabuki syndrome (short stature, intellectual disability, long palpebral fissures with eversion of lateral portion of lower lid).

Other features of the eyes should be noted. The obliquity (slant) of the palpebral fissures may be upward (as in Down syndrome [Figure 148-3]) or downward (as in Treacher Collins syndrome [Figure 148-4] or Noonan syndrome [Figure 148-5]). The presence of epicanthal folds—flaps of skin covering the inner canthus of the eye, usually associated with flattening of the nasal bridge—may indicate Down syndrome or fetal alcohol syndrome.

Features of the nose—especially the nasal bridge, which can be flattened in Down syndrome or prominent as in velocardiofacial syndrome—should be noted. Are the nares oriented normally, or are they tipped back (a condition known as anteversion)? Is the body of the nose normal, or is it deficient?

**Figure 148-2** Smooth philtrum, characteristic of fetal alcohol syndrome. (From Hoyme HE. *Assessing dysmorphism in primary care*. In: Saul RA, ed. *Medical Genetics in Pediatric Practice*. Elk Grove Village, IL: American Academy of Pediatrics; 2013:135–174. Courtesy of Greenwood Genetic Center, Greenwood, SC.)

**Figure 148-3** Upslanted palpebral fissures, characteristic of Down syndrome. (From Hoyme HE. *Assessing dysmorphism in primary care*. In: Saul RA, ed. *Medical Genetics in Pediatric Practice*. Elk Grove Village, IL: American Academy of Pediatrics; 2013:135–174. Courtesy of Greenwood Genetic Center, Greenwood, SC.)

**Figure 148-4** Treacher Collins syndrome. (Courtesy of Marilyn Jones, MD)

**Figure 148-5** Downslanted palpebral fissures, characteristic of Noonan syndrome. (From Hoyme HE. *Assessing dysmorphology in primary care*. In: Saul RA, ed. *Medical Genetics in Pediatric Practice*. Elk Grove Village, IL: American Academy of Pediatrics; 2013:135–174. Courtesy of Greenwood Genetic Center, Greenwood, SC.)

In evaluating the malar region, the ears should be checked for size (measured and plotted on growth charts that record length for age), shape (noting abnormal folding or flattening of the helices), position (ears are described as low set if the top of the ear is below a line drawn from the outer canthus to the occiput) and orientation (posterior rotation is present

**Figure 148-6** Webbed neck, characteristic of Turner syndrome. (From Hoyme HE. *Assessing dysmorphology in primary care*. In: Saul RA, ed. *Medical Genetics in Pediatric Practice*. Elk Grove Village, IL: American Academy of Pediatrics; 2013:135–174. Courtesy of Lynne Bird, MD.)

when the ear seems to be turned toward the rear of the head). Ears may be low set because they are small (or microtic) or because of a malformation of the mandibular region.

Finally, the examiner should evaluate the mandibular region, the area encompassing the lower portions of each ear and including the lower jaw. In most newborns, the chin is retruded (slightly set back behind the vertical line extending from the forehead to the philtrum). If the mandible itself is small, then it is described as micrognathic, whereas an unusually prominent mandible is described as prognathic. Significant micrognathia is seen in the Pierre Robin malformation sequence.

#### Remainder of the Body

Once facial dysmorphic features have been detected, the primary care physician must conduct a thorough examination looking for additional unusual findings. Again, findings may point to a specific diagnosis.

**NECK.** Examination of the neck may reveal webbing, a feature common in Turner (Figure 148-6) and Noonan syndromes, or shortening, as is occasionally seen in some skeletal dysplasias and in conditions in which anomalies of the cervical spine occur, such as Klippel-Feil syndrome. The position of the posterior hairline should also be evaluated, and the size of the thyroid gland should be assessed.

**TRUNK.** The chest should be examined for shape (a shieldlike chest is found in Noonan and Turner syndromes) and symmetry (hypoplasia of the pectoralis major and minor muscles, leading to asymmetry, is a feature of the Poland malformation sequence). A pectus deformity of the chest (either pectus excavatum

or pectus carinatum) is usually an isolated finding but is a cardinal feature of Marfan syndrome. Scoliosis, also usually an isolated feature, is often seen in individuals with Marfan syndrome, as well as in several other disorders.

**EXTREMITIES.** Anomalies of the extremities are common in many congenital malformation syndromes. All joints should be examined for range of motion. The presence of single or multiple joint contractures suggests either intrinsic neuromuscular dysfunction, as in the case of some forms of muscular dystrophy, or external deforming forces that limited motion of the joint in utero. Radioulnar synostosis, an inability to pronate or supinate the elbow, occurs in fetal alcohol syndrome and in some X chromosome aneuploidy syndromes (such as 48, XXXX and 48, XXXY syndromes).

Next, the hands should be examined. Polydactyly (the presence of extra digits) occurs in isolation as an autosomal dominant trait in up to 1% of all newborns, but can also be seen as part of a malformation syndrome such as trisomy 13. Oligodactyly (a deficiency in the number of digits) is seen in Fanconi syndrome (growth restriction, aplastic anemia, development of leukemia or lymphoma and associated heart, renal and limb defects, including radial aplasia and thumb malformation or aplasia), in which it is generally part of a more severe limb reduction defect, or secondary to intrauterine amputation that may occur with *amniotic band disruption sequence* (Figure 148-7). Syndactyly (a joining of 2 or more digits) is also common to several syndromes, including Smith-Lemli-Opitz syndrome.

Dermatoglyphics, especially the palmar crease pattern, are also important to note. A transverse palmar crease (Figure 148-8), indicative of hypotonia during early fetal life, is seen in approximately 50% of children with Down syndrome (and 10% of individuals in the general population). A characteristic palmar crease pattern is also seen in fetal alcohol syndrome.

**GENITALIA.** Genitalia should be examined for abnormalities in structure. In male infants, if the penis seems short, then it should be measured and plotted on an appropriate growth chart. Ambiguous genitalia can be associated with endocrinologic disorders such as congenital adrenal hyperplasia (female infants have masculinized external genitalia, but male genitalis may be unaffected), chromosomal disorders such as Turner syndrome mosaicism, or part of a multiple malformation disorder such as Smith-Lemli-Opitz syndrome. Although hypospadias, which occurs in 1 in 300 male newborns, is a common congenital malformation that often occurs as an isolated defect, if it is associated with other anomalies, then the possibility of a syndrome is strong.

### Laboratory Evaluation

Following completion of the medical history, family history, and physical examination, the dysmorphologist takes the clues that have been gathered and attempts to solve the puzzle by assembling them into a diagnosis. The differential diagnosis is made up of conditions that feature some or all of the clues. Once this list has been assembled, a series of laboratory and

**Figure 148-7** Amniotic bands. (From Hoyme HE. *Assessing dysmorphism in primary care*. In: Saul RA, ed. *Medical Genetics in Pediatric Practice*. Elk Grove Village, IL: American Academy of Pediatrics; 2013:135–174.)

**Figure 148-8** Single palmar crease. (From Hoyme HE. *Assessing dysmorphism in primary care*. In: Saul RA, ed. *Medical Genetics in Pediatric Practice*. Elk Grove Village, IL: American Academy of Pediatrics; 2013:135–174. Courtesy of Lynne Bird, MD.)

imaging tests can be performed in an attempt to arrive at a definitive diagnosis. Typical tests used by the dysmorphologist are outlined here.

Chromosomal microarray analysis (CMA), should be routinely ordered for children with

- Multiple congenital anomalies
- The involvement of 1 major organ system and 2 or more dysmorphic features
- The presence of intellectual disability
- The presence of an autism spectrum disorder

Chromosome analysis (karyotype) will identify conditions caused by too much chromosomal material

(ie, trisomies) or those with too little chromosomal material (ie, monosomies). However, karyotype will only identify large abnormalities. Chromosomal microarray uses DNA technology to identify smaller partial trisomies or monosomies than can be seen by karyotype, making it about 4 to 5 times more sensitive. This technique compares the amount of DNA from the patient to that of a control, looking for changes in the number of DNA copies. It is able to look for copy number changes throughout the genome. CMA will not identify balanced rearrangements such as translocations or inversions, so if this is suspected, karyotype should be ordered.

Fluorescent in situ hybridization (FISH) uses DNA technology to identify specific regions of the genome that are either missing or duplicated. FISH uses a DNA probe that is complementary to a specific region of the genome. After a fluorescent marker is attached to this probe, it is incubated with chromosomal DNA from the patient. If the sequence is present in the patient, then the probe will hybridize, its presence announced by the appearance of the bound fluorescent marker.

A FISH study is requested when a syndrome with a known chromosomal defect is suspected. Such disorders as velocardiofacial syndrome (deletion of *22q11.2*), Prader-Willi syndrome (deletion of *15q11.2*), Angelman syndrome (deletion of *15q11.2*), and Beckwith-Wiedemann syndrome (duplication of *11p15.2*) are included in this group. It may also be used to confirm findings of a CMA.

In a growing number of disorders, *direct DNA* analysis can be performed to identify specific mutations known to cause disease. Because the list of these disorders increases every day, using Web-based resources for the most recent information is necessary. An extremely helpful Web site is [www.genetests.org](http://www.genetests.org). Frequently updated, Genetests provides information about the availability of testing for specific conditions and identifies laboratories performing the testing. Newer technologies, termed next-generation sequencing, are emerging that perform DNA analysis of multiple genes in a single test. These emerging techniques, including whole exome sequencing and whole genome sequencing, will allow for better diagnosis of disorders caused by multiple genes, and the identification of genes for disease in which the cause remains elusive.

Radiologic imaging plays an important role in the evaluation of children with dysmorphic features. Individuals found to have multiple external malformations should have a thorough evaluation to search for the presence of internal malformations. Testing might include ultrasound evaluations of the head and abdomen, the latter area to look for anomalies in the kidney, bladder, liver, and spleen. Skeletal radiographs should be taken if concern exists about a possible skeletal dysplasia. The presence of a heart murmur should trigger a cardiology consultation, and an electrocardiogram and echocardiogram may be indicated. Magnetic resonance imaging may be indicated in children with neurologic abnormalities or spinal defects. The presence of craniosynostosis indicates the need for a 3-dimensionally reconstructed computed tomographic scan of the head.

## DIAGNOSIS

Although the presence of characteristic findings may sometimes make the definitive diagnosis of a malformation syndrome simple, in most cases no specific diagnosis is immediately evident. Some constellations of findings are rare, and finding a match may prove difficult. In many cases, all laboratory tests are normal, and confirmation relies on subjective findings. Clinical geneticists have attempted to resolve this difficulty by developing scoring systems, cross-referenced tables of anomalies that help in developing a differential diagnosis, and even computerized diagnostic programs.

An accurate diagnosis is important for 3 reasons as follows:

1. It offers the family an explanation of why their child was born with congenital anomalies. This information may help allay feelings of guilt, given that parents often believe that they are responsible for their child's problem.
2. The natural history of many disorders is well described; as such, a diagnosis allows the physician to anticipate medical problems associated with a particular syndrome and to perform appropriate screening. A diagnosis may also provide reassurance that other medical problems are no more likely to occur than they might with other children who do not have the diagnosis.
3. It permits accurate recurrence risk for future progeny; only after a diagnosis is confirmed can genetic counseling and, eventually, preimplantation genetic diagnosis or prenatal diagnostic testing be performed.

Once a definitive diagnosis has been made, the dysmorphologist must meet with the family in person to explain the condition and the prognosis. Such meetings are often difficult, since this is the moment that the news is first delivered to the parents and the full effect of the child's condition is realized. A sufficient amount of time should be allotted for this meeting because families may have many questions, and each question should be answered in a thoughtful and considerate way. It is also often helpful to include social support professionals as participants in these meetings; genetic counselors, social workers and psychologists can help the family accept the news and begin moving on with the next phase of their lives.

The diagnosis also enables the physician to provide the family with educational materials about their child's condition. Additionally, many condition-specific support groups exist and the physician can provide the family with information about such groups in their area. These groups offer social and emotional assistance for the family of a child with a newly diagnosed genetic disorder. The Internet has become an important source for parents seeking information about their child's condition, but care should be exercised because information on the Internet is not always subject to editorial control, and some of the information may be inaccurate, or at times misleading or inappropriate. Physicians should try to screen Web sites before they suggest them to the family. Some recommendations of Web sites can be found in the Tools for Practice section at the end of this chapter.

## SUMMARY

The physician confronted with a patient who has dysmorphic facial features must decide whether the patient or family will benefit from a thorough evaluation or referral. The most important task initially is to determine whether the features are consistent with the individual's genetic background or whether they represent an abnormal phenotype. Through systematic gathering of information, the physician should attempt to establish an etiologic diagnosis and then convey the implications (including genetic counseling) to the appropriate family members.

## Chapter 149

# FAILURE TO THRIVE: PEDIATRIC UNDERNUTRITION

Andrew D. Racine, MD, PhD

The unfortunate term *failure to thrive* has burdened generations of physicians and their patients as an unenlightening phrase that combines a heterogeneous group of infants and young children with nothing more in common than a growth pattern irreconcilable with a predetermined standard for age. Abnormalities ranging from congestive heart failure to psychosocial deprivation can eventually lead to the same place, called failure to thrive. To find a child in such a location, however, tells us little about the

direction from which he or she strayed to come to our attention. Moreover, the term failure to thrive is as pejorative as it is devoid of content; thus, recent scholarship has favored phrases such as *pediatric undernutrition*, as used in the *Bright Futures in Practice* literature, or *weight faltering*, as adopted by our British colleagues.

Given the diversity of potential causes, evaluation and management of a child who fails to gain weight adequately represent a formidable challenge that requires of the physician:

- A determination to listen attentively and examine thoroughly, given that no adequate substitute has yet been found for a complete history and physical examination
- A broad familiarity with the many pathophysiologic sequences that can give rise to this condition
- An understanding of healthy infant behavior and development to identify aberrancies that may threaten weight gain at different ages
- A capacity to gather and synthesize information about the physical, psychological, emotional, familial, and social contexts of the patient's presentation
- A willingness to work with a team of other medical professionals to evaluate and manage the child
- The patience to persevere for as long as required to establish adequate weight gain

## DEFINITION

A diagnosis generally signals the culmination of a process of evaluation. By contrast, the diagnosis of failure to thrive merely serves to *initiate* the evaluation of a patient who has an abnormal pattern of weight gain. Deviation from normal weight gain has been defined conventionally by reference to age-adjusted nationally standardized norms of weight and rate of weight gain. Infants or young children who either fall below a given weight-for-age or weight-for-height percentile, or whose rate of weight gain has declined across 2 major percentiles (ie, 90th, 75th, 50th, 25th, 10th, or 5th) invite close scrutiny. The Social Security Administration, for example, defines failure to thrive as a fall in weight to below the third percentile or to less than 75% of the median weight-for-height or weight-for-age percentile in children younger than 2 years.

Static measurements of a child's weight-for-age or weight-for-height percentile that document a child's *size* should be distinguished from repeated measurements over time that record a child's *growth*. A deviation from the norm in size may or may not, depending on the clinical circumstances, indicate an abnormality of growth.

A clinical entity defined by reference to statistical norms merits some additional comment. First, although an occasional child may have obvious signs of severe malnutrition at the initial examination, a single observation of weight in a child is generally insufficient to make any diagnosis. The concern here, for the most part, is with children who exhibit abnormal patterns of weight gain over time.

Second, although the aim is to identify children whose weight or weight gain is abnormal, some

children will fall into the extreme tails of the standard distributions, be it 10%, 5%, or 3%, of any cohort. The farther out on the curve we observe any individual child, however, the more likely the child is to be truly abnormal with respect to weight-for-age or weight-for-height percentile.

Third, the national reference charts for children's anthropometric measurements are constructed by using serial cross-sections of children, not longitudinal observations of cohorts as they grow. Therefore, the rate at which a child gains weight individually will differ from tracks across collections of different children at different ages that appear on these charts. Over time, children's weights generally regress toward the mean, with heavier infants gaining weight at slower rates than lighter infants. To account for this pattern, British researchers developed weight charts from a cohort of 3,418 full-term infants from Newcastle based on standard deviations of weight changes over time. These charts have wider percentile channels at upper weights and narrower channels at lower weights.

Finally, statistical descriptions must not be allowed to obscure the salient feature common to most children who fail to gain weight adequately: they suffer from malnutrition and are therefore at risk for its attendant consequences. When acute malnutrition results in decreased weight-for-age percentile, the condition is referred to as *wasting*. If caloric deprivation is prolonged, it will eventually affect the child's linear growth, at which point the child is said to be *stunted*. Abnormalities in linear growth not accompanied by wasting (the child who has short stature alone) are not the subject of failure to thrive.

One common set of criteria defines failure to thrive in children younger than 2 years as

- Weight consistently less than 80% of the median for age, or
- Weight on more than 1 occasion falling below the third percentile for age, or
- Weight that has fallen across 2 major percentiles on growth charts

Until 2006, the instruments most commonly used to track children's height, weight, and head circumference were growth charts published by the National Center for Health Statistics (NCHS) of the Centers for Disease Control and Prevention (CDC) based on data collected on children in the United States between the years 1963 and 1994. These data reflected the actual growth of infants and children from a fairly homogeneous population with respect to its racial composition and also depicted the weights of a population most of whose members were formula fed.

In response to these and other shortcomings, in 2006 an expert panel with representatives from the CDC, the National Institutes of Health, and the American Academy of Pediatrics recommended adoption of the international growth charts for children 0 to 24 months of age released that year by the World Health Organization (WHO). The data used to compile these charts were collected between 1997 and 2003 from six sites around the world. These charts are described as representing *standards*, meaning that they capture "... the growth of healthy children in optimal conditions," rather than the reference charts from the

NCHS that they were designed to replace, which described "... how certain children grew in a particular place and time." The expert panel recommended continued use of the older NCHS charts for children 24 to 59 months, where discrepancies between the NCHS and WHO charts were felt to be negligible.

Common cutoff values used to identify children in need of more intense scrutiny differ between the NCHS charts and the WHO charts. The accepted value used with the NCHS charts is the 5th percentile, whereas the recommendation based on the WHO charts suggests concentrating on infants who fall below the 2.3rd percentile. Thus, although the older NCHS reference charts could have been anticipated to identify as many as 10% of children seen in outpatient settings and 3% to 5% of hospital admissions, those fulfilling equivalent criteria using the WHO cutoffs are likely to be less numerous. Children who exhibit weights from 61% to 75% of the median for age on the new charts are fewer still but require intensive outpatient monitoring. When a child's weight falls below 60% of the median for age on the new charts, the associated morbidity is severe and warrants inpatient hospitalization. Children from lower socioeconomic backgrounds may be at heightened risk for malnutrition and consequent wasting.

## HEALTHY WEIGHT GAIN IN INFANTS

Both the NCHS and the WHO growth charts have received widespread application as tools for plotting the growth patterns of healthy infants and children. The ease of their use makes them ideal screening instruments, but, as with all screening tools, their sensitivity and specificity are limited. They do not, for example, take into account parental size or the presence of pre-existing chromosomal abnormalities, leading some researchers to argue for the use of standards that control for mean parental height or the presence of certain genetic conditions such as trisomy 21. The *Bright Futures* publication on nutrition provides references for growth charts based on specific disorders.

Recent studies examined the rate at which infants gain weight and how regression to the mean reflects the tendency of some heavier infants to gain weight more slowly and some lighter infants to gain weight more quickly over time. The mean weight of a newborn is approximately 3.25 kg ( $\pm 0.9$  kg.). Many infants lose between 6% and 10% of this weight in the first week as they undergo the normal diuresis associated with adaptation to the extrauterine environment. Birth weight usually is regained by the age of 10 days. Because a newborn's weight at birth predominantly reflects the influence of maternal characteristics and the intrauterine environment, it is an imperfect reflection of genetic growth potential. By 4 to 8 weeks of age, however, much catch-up growth in babies born "light for dates" has already occurred; thus, an infant's weight at this time seems to be a more reliable predictor than birth weight or weight at 12 months. In general, infants can be expected to gain a mean of 30 g ( $\pm 15$  g) a day during the first 3 months of life. Infants will usually triple their birth weight by 1 year of age, at which time the mean daily weight gain has declined to approximately 10 g ( $\pm 3$  g). Characteristics

of maternal and child feeding behaviors may have important influence on the rate of weight gain in the first year of life among subpopulations of infants with feeding difficulties.

## **PATHOGENESIS**

Infants and children grow in the presence of adequate amounts of 4 fundamental constituents: oxygen, substrate, hormones, and love. Deficiency of any one or a combination of these impedes normal weight gain. Oxygen deprivation at the tissue level from causes as diverse as congestive heart failure, chronic lung disease, or anemia will result in poor weight gain. Inadequate calories, protein, or micronutrients either from environmental deprivation, malabsorption, or inability to metabolize them at the tissue level also inhibit normal weight gain. Deficiencies in growth hormone, insulin-like growth factors, glucocorticoids, thyroid hormone, and other regulators of growth can result in failure to thrive. Finally, infants or children severely deprived of affection will often not grow despite what appears to be normal caloric intake. Chronic disease from many causes will interrupt normal weight gain through the induction of anorexia, malabsorption, increased metabolic needs, and the elaboration of inflammatory mediators, including tumor necrosis factor. Children with chromosomal or other genetic abnormalities, although they may exhibit idiosyncratic growth patterns specific to their particular condition, will also attain their full growth potential only in the presence of these critical ingredients.

In the past, patients with inadequate weight gain were classified as a minority whose difficulty stemmed from a readily identifiable *organic* cause, and a majority whose problem was categorized as *nonorganic*. Other researchers emphasized the overlapping nature of these distinctions and have suggested a third, or *mixed*, category of failure to thrive. More recent approaches have tended to depart from the organic–nonorganic dichotomy in recognition of the somewhat arbitrary nature of this distinction.

A more useful categorization of infants and children who have inadequate weight gain acknowledges an imbalance between the energy needs of the organism that does not grow and the energy at its disposition. The largest share of energy consumed, about 55% to 60%, is devoted to maintaining a basal metabolic rate. An additional 5% to 10% of energy is lost in urine and stool, 5% is accounted for by specific dynamic action, 15% is used for normal physical activity above basal metabolic functions, and 15% is directed toward growth. To provide for all these functions, infants need approximately 100 to 110 kcal/kg/day.

An imbalance between energy needs and energy supplies can arise either from increases in the former or deficiencies in the latter. Box 149-1 lists conditions that increase the energy needs of the organism. Energy needs increase either with increases in the intensity of energy expenditure or decreases in the efficiency of energy use. Conditions that increase the intensity of energy expenditure include chronic heart disease, chronic lung disease, chronic anemia, chronic infection, certain endocrine abnormalities, malignancy, and intoxications. The efficiency of energy

### **BOX 149-1 That Increase Energy Needs**

#### **INCREASED INTENSITY OF ENERGY UTILIZATION**

- Chronic heart disease (congenital or acquired)
- Chronic lung disease (bronchopulmonary dysplasia, cystic fibrosis, pulmonary lymphangiectasis)
- Chronic anemia (hemoglobinopathies, enzyme deficiencies, membrane abnormalities)
- Chronic infection (urinary tract infections, respiratory infections, tuberculosis)
- Endocrine abnormalities (hyperthyroidism)
- Malignancy (neuroblastoma, ganglioneuroma)

#### **DRUGS OR TOXINS OR DECREASED EFFICIENCY OF ENERGY UTILIZATION**

- Chronic infection
- Chronic renal disease
- Hepatic insufficiency (cirrhosis)
- Metabolic disease (disorders of amino acid or carbohydrate metabolism, idiopathic hypercalcemia of infancy)
- Hormonal disturbances (hypopituitarism, hypoparathyroidism, chronic adrenocortical insufficiency, diabetes insipidus, hypothyroidism)
- Genetic conditions (Down syndrome, de Lange syndrome, cri du chat syndrome, Smith-Lemli-Opitz syndrome, familial dysautonomia)
- Micronutrient deficiencies (iron, zinc, carnitine)

utilization can be compromised by chronic infection, chronic renal disease, hepatic insufficiency, inborn errors of metabolism, hormonal abnormalities, certain genetic syndromes, and deficiencies of various micronutrients, including iron, zinc, and carnitine.

Conditions leading to deficiency in energy supply are listed in Box 149-2. These conditions originate because calories are either withheld from or improperly presented to the child because they are refused, vomited, not ingested, or not absorbed.

In the category of caloric deprivation, nutritional deprivation in utero that may result in permanent growth restriction must be included. After delivery, a newborn may not receive sufficient calories because of parenting difficulties ranging from unfamiliarity with proper preparation of infant formula or appropriate breastfeeding techniques, to psychosocial dysfunction, to maternal depression, and even to frank abuse or neglect. Other conditions that fall into this category include economic deprivation, unsound parental beliefs regarding nutrition, and subtle central nervous system abnormalities in the child causing him or her to be a difficult feeder.

Food refusal in children, beginning even in infancy, can result from many causes, including pain (from reflux esophagitis), psychosocial adjustment disorders from emotional deprivation, anorexia from chronic infection or intoxication, and structural abnormalities resulting in dysphagia. Structural malformations of the nose or oropharynx, such as cleft palate, choanal

**BOX 149-2 Conditions That Result in Deficient Energy Supply**

- Calories withheld
- In utero conditions
- Formula preparation mistakes
- Breastfeeding difficulties
- Parent–child psychosocial dysfunction
- Maternal depression
- Intentional abuse or neglect
- Poverty
- Unsound parental beliefs regarding nutrition
- Feeding difficulties
- Calories not properly ingested or digested
- Oral pain caused by dental disease
- Anorexia (reflux esophagitis, emotional deprivation, chronic infection, dysphagia)
- Structural abnormalities of the oropharynx or nasopharynx (cleft palate, choanal atresia, Treacher Collins syndrome, Pierre Robin syndrome, laryngeal web)
- Structural abnormalities of the gastrointestinal tract (stenosis or atresia of the esophagus or duodenum, tracheoesophageal fistula, vascular ring, strictures, achalasia, malrotation, antral web, pyloric stenosis)
- Neuromuscular disorders (cerebral palsy, hydrocephalus, myopathies)
- Conditions leading to excessive dyspnea (congestive heart failure, chronic lung disease)
- Vomiting and rumination
- Malabsorption
- Small bowel disease (celiac disease, inflammatory bowel disease, disaccharide malabsorption, intestinal lymphangiectasia, jejunal atresia, duplication cysts, chronic parasitic infections)
- Pancreatic disease (cystic fibrosis, Shwachman-Diamond syndrome, chronic pancreatitis)
- Liver disease (cirrhosis, intrahepatic cholestatic syndromes, biliary atresia)

atresia, or Treacher Collins syndrome, can lead to an inability to ingest nutrients properly, as can muscular weakness, cerebral palsy or other central nervous system abnormalities, and diseases that give rise to excessive dyspnea.

Vomiting caused by structural abnormalities of the gastrointestinal tract, increased intracranial pressure from any source, chronic acidosis, rumination, and gastroesophageal reflux may all impede growth through caloric deprivation.

The principal organ of nutrient absorption is the small bowel. Malabsorption can occur from gross structural abnormalities, inflammatory conditions, infectious agents, or disorders of organs that elaborate enzymes essential for digestion.

In consideration of these potential causes for inadequate weight gain, 2 cardinal principles should be emphasized. First, most cases encountered in ambulatory practice will result from inadequate caloric intake,

with most of these originating in a disturbance in the parent–child feeding behavior. At one time, maternal mental health disorders were thought to account for the majority of these cases. The particular issue of maternal depression as a risk factor for failure to gain weight in infancy has received wide attention in the literature. Although case-control studies have indicated a possible association between these 2 conditions, more definitive population-based cohort studies have failed to confirm this finding. Recent analysis dissected a more subtle web of causation. The term *transactional model* allows for the complex interplay of social conditions, family interactions, and individual psychodynamics in creating feeding abnormalities. The salient feature that distinguishes infants in this category who do not gain weight at the same rate as their peers is that they take in foods with less total energy.

Second, a thorough history and physical examination is the surest route to diagnosis for the residual minority of cases not caused by caloric insufficiency. If the cause of the problem is not made clear by history and physical examination, then laboratory investigation is unlikely to reveal it.

## EVALUATION

Prompt evaluation of infants and children who do not gain weight as expected is important. The history and physical examination should be directed toward certain areas (see later discussion), and in cases in which psychosocial features predominate, most laboratory tests may be unnecessary.

## HISTORY

### Initial Approach

Every evaluation of an infant or child who is not gaining weight must begin with a thorough history. Although the history and physical examination will usually be conducted in the office, a home visit affords the pediatrician an opportunity to observe the family interaction around feeding in the context in which it normally occurs. A history of the present illness should assemble all data available from previous anthropometric measurements of the patient, including weight, height, and head circumference. Premature infants should have their measurements corrected for gestational age until 18 months of age for head circumference, 24 months of age for weight, and 40 months of age for height. The physician should begin by asking the principal caregivers how they think the baby is doing and what they believe is the problem. Knowledge of a parent's frame of mind may propel further evaluation toward or away from difficulty in parent–child interaction, including child neglect, as a potential explanation for a child's lack of weight gain.

### Feeding

A thorough feeding history is essential. Is the baby bottle fed or breastfed? How often does the child breastfeed, and for how long? Does the mother feel as though the child is sucking well, and does the baby appear satiated after he or she feeds? If bottle fed, how in detail is the formula prepared and by whom? What

is the baby's sleep pattern, and how many ounces will the baby take in a 24-hour period? Does the infant wet 6 to 8 diapers a day? Consider observing a feeding, which can be done while taking the history.

For older children, when were solids introduced? Does the parent find the child to be a *picky eater* or difficult to interest in food? Does the child drink excessive amounts of juice during the day, substituting for more calorie-rich nutrients? What are meal times like at home? Where does the child eat, and with whom? Are distractions, such as television or video games, present during meals? Is food being used for discipline or in battles over control? A 24-hour dietary recall of a typical day can often help quantify the caloric intake of the patient. If this information proves difficult to elicit, then the parents can be sent home with a nutritional diary to fill out prospectively and bring in at the next visit.

### Vomiting

The physician should inquire about any vomiting or spitting up, being sure to explore frequency, volume, and presence of blood or bile in the emesis. Gastric outlet obstructions (pyloric stenosis, antral web) often result in the generation of significant propulsive forces leading to projectile vomiting, whereas gastroesophageal reflux often results in less dramatic patterns of regurgitation. An obstruction distal to the ligament of Treitz will generally produce bilious vomiting, a symptom that must be taken with utmost seriousness in infancy because it may indicate the presence of a malrotation and midgut volvulus.

### Stools

The pattern and frequency of stooling must not be overlooked in the history of present illness. The child who has liquid stools may have a small-bowel pathologic condition, and bulky, foul-smelling stools may result from fat malabsorption. If mucus or blood is in the stools, an inflammatory condition may be present.

### Medical History

Additional information should be obtained as part of the medical history, beginning with the parents' attitudes regarding their decision to have a baby and what their experience with the pregnancy was like. Did the mother gain a reasonable amount of weight? Did she experience any illnesses during her pregnancy? Hypertension or preeclampsia will result in an infant who is small for gestational age; gestational diabetes may produce an infant with macrosomia who fails to gain weight because of postnatal cardiac complications.

The physician should ask about specific toxic exposures in utero, particularly to tobacco, marijuana, and alcohol. Tobacco may result in a small baby who rapidly catches up in weight with her peers, whereas marijuana and alcohol exert an influence on growth that may be sustained throughout childhood. Recording the child's gestational age at birth, any unusual complications of the labor and delivery, and the presence of malformations or other obvious deformities will complete this portion of the history.

### Family History

A family history should document the growth patterns of siblings; record the occurrence of fetal loss or infant deaths; review the presence in the family of immune deficiencies, neurologic disorders, or metabolic derangements; and highlight any unexplained growth deficiencies in close relatives. These findings may provide clues to the cause of the growth abnormality in the child. The results of recent comprehensive longitudinal studies from England emphasize the extent to which mean parental height and parity overwhelm the influence of traditional markers of socioeconomic deprivation that includes parental education or occupational status on the weight gain of young infants.

### Social History

The social history should focus on the availability of social supports for the parents, the existence of economic or legal circumstances that threaten the stability of the family, the nature of the relationship between the parents, and the presence of affective disorders, particularly depression, in either the mother or father. Is there substance abuse in the home, either of alcohol or drugs? Any recent disruptive events in the family's life should be explored to determine what effect they may have had on the parents' ability to care for the patient. Has there been any involvement of the family with child protective services? Finally, at this point, the physician may uncover unrealistic expectations that parents harbor regarding feeding patterns, dietary fads, or behavior in infancy, all of which provide clues to why feeding this infant developed into such a challenge.

## PHYSICAL EXAMINATION

Repeated anthropometric measurements over time constitute the most important component of the physical evaluation of children who are not gaining weight. On the initial examination, the physician should begin with observing the child's general relatedness to the parents and the examiner. Does the child appear listless, easily distractible, or irritable? Can he or she be engaged to make eye contact or to play with an age-appropriate toy? With the child completely undressed, a notation should be made of any evidence of wasting, of the presence and distribution of normal subcutaneous body fat, of muscle mass and tone, and of the presence of dysmorphic features. These observations will serve to set the stage for more detailed examination.

Particular attention should be paid to organ systems that may reflect evidence of malnutrition. The mucous membranes, hair, nails, and skin develop abnormalities in the presence of vitamin, protein, fat, and micronutrient deficiencies. The head, eyes, ears, nose, and throat may reveal conditions ranging from open fontanelles of hypothyroidism or craniotabes of nutritional rickets to the blurred disk margins of increased intracranial pressure in a child who has chronic emesis or a submucosal cleft of the hard palate in an infant who feeds poorly. Examination of the mouth may reveal extensive dental disease or a dental abscess that can be causing severe pain on oral intake.

The thyroid should be palpated gently and then auscultated for evidence of hyperthyroidism. Examination of the heart and lungs, with observation, palpation, and particularly auscultation, may reveal wheezing, rales, or heart murmurs suggestive of chronic conditions, which often result in substantial energy expenditures that outstrip the supply of nutrients available to the infant. Examination of the digits for clubbing in the older child should not be neglected. A thorough abdominal examination will identify organomegaly associated with tumor, infection, or storage disease. Intestinal distention can be associated with carbohydrate malabsorption from various causes. The neurologic examination may suggest explanations for an infant's inability to ingest adequate calories: disorders of mentation, cranial nerve abnormalities, generalized weakness, or spasticity should be carefully sought.

With infants who are not gaining weight, it can be very informative to observe a feeding. Does the parent make meaningful eye contact with the child and burp the baby appropriately? If there is any question about the adequacy of the baby's swallowing, an assessment by a speech therapist for the efficiency and safety of the swallow can be helpful.

## LABORATORY EVALUATION

In the absence of evidence from the history or physical examination indicating the need for specific laboratory testing, expectations of the yield of laboratory investigation should be modest. When charts of 185 patients who were hospitalized for failure to thrive at the Children's Hospital of Buffalo were reviewed, only 1.4% of the laboratory studies performed were found to be of diagnostic value. A similar review of 122 infants who were hospitalized at the Boston Children's Hospital revealed that a mean of 40 laboratory tests were ordered, but only 0.8% revealed an abnormality that contributed to a diagnosis.

If the cause of a child's failure to gain weight adequately remains uncertain after careful history and physical examination, then a limited number of screening studies might be considered, including a complete blood count, a blood pH, serum electrolytes, blood urea nitrogen and creatinine, a urinalysis and urine culture, and an examination of the stool for reducing substances, pH, occult blood, and ova and parasites. More extensive testing for malabsorption, endocrine disorders, occult infection, malignancy, and cardiac, pulmonary, or renal abnormalities should be done only when historical or physical examination evidence of these diagnoses is present.

## THERAPY AND FOLLOW-UP

The therapeutic approach to children failing to gain weight adequately must be tailored to the individual needs of the family and the child. For infants and children in whom a specific diagnosis was identified, therapy should be directed toward the underlying disease or condition. A disturbance in the parent-child interaction will more often be recognized as the cause of the patient's inability to gain weight. Children exhibiting food avoidance behaviors may respond well

to interventions that involve differential rewards aimed at extinguishing problematic interactions. Regardless of the underlying cause, the family should be approached nonjudgmentally, and the severity of the child's condition should dictate the initial approach to therapy.

## Mild to Moderate Undernutrition

The pediatrician, with consultation from a nutritionist, can manage infants and children exhibiting mild degrees of malnutrition (greater than 80% of ideal body weight for age) as outpatients, with occasional consultation from subspecialist colleagues. Patients who have evidence of more severe caloric deprivation will require the involvement of a multidisciplinary team, including the pediatrician, nutritionist, mental health or behavioral therapist, and social worker. Hospitalization may be necessary for a subset of these patients whose malnutrition is combined with or results from another significant medical condition. Home visitation using professionals has been demonstrated to be a useful intervention in select circumstances. Others, however, have achieved less success in generating improved weight gain with this intervention despite its other notable benefits. Child protective services must be alerted about any child thought to be the victim of neglect.

The goals of management must focus on nutritional rehabilitation, parental education, and behavioral intervention. Attempts to overfeed malnourished infants at the outset of therapy should be avoided because initially they may exhibit some degree of anorexia, and refeeding that is too vigorous may induce malabsorption and diarrhea. The refeeding regimen should be calculated to provide about 10% to 15% of calories from protein, 50% to 60% from carbohydrate, and 30% to 40% from fat.

A typical 3-phase regimen may begin with provision of 100% of daily age-adjusted energy and protein requirements based on the child's weight on day 1.

If this phase is well tolerated, in phase 2 intake is then increased to provide adequate nutrition to achieve catch-up growth. Multiplying the age-adjusted energy requirements (kcal/kg/day) by the ratio of the child's ideal body weight for height divided by the child's actual body weight at presentation will generate a reasonable estimate of the nutritional requirements for this stage. The same calculation can be made for protein requirements (Box 149-3). In most instances, the energy and protein requirements for these phases of infant refeeding can be accomplished with the use of a routine infant formula modified to increase its caloric density. Mixing 13 oz of concentrated formula with 10 oz of water rather than 13 oz of water will create a formula that is 24 cal/oz, as will mixing 3 scoops of powdered formula with 5 ounces of water. Alternatively, the use of carbohydrate in the form of glucose polymers or fat in the form of medium-chain triglycerides will add calories while avoiding the complications of overhydration. For older children, the repertoire of caloric supplements will include a wide variety of solid foods as well.

In the third, or consolidation, phase of nutritional rehabilitation, a varied diet is offered ad libitum as the

**BOX 149-3 Sample Rehabilitation Schedule for Undernutrition**

Scenario: A 6-month-old boy with poor weight gain is referred for nutritional rehabilitation. He currently weighs 5.5 kg and is 67 cm in length. The 50th percentile weight for this length is 7.7 kg, putting

the infant at 71% of the ideal body weight for height.

Normal adjustment catch-up requirements include the following:

	REQUIREMENT		FACTOR		REQUIREMENT
Calorie supplementation	100 kcal/kg/day	×	7.7 / 5.5	=	140 kcal/kg/day
Protein supplementation	2 g/kg/day	×	7.7 / 5.5	=	2.8 g/kg/day

Adding a multivitamin with iron to this child's regimen would be advisable.

child gradually approaches ideal body weight. Multivitamin and iron supplementation should be part of every refeeding regimen for undernourished children.

Initiation of nutritional rehabilitation is an ideal time to engage the parents in an educational program that focuses on family interactions, psychological vulnerabilities, and social needs. Emphasis should be placed on appropriate nutritional information, and concrete suggestions should be offered about how to structure mealtime at home to minimize distractions in a relaxed social environment that encourages good eating habits. For families in need, access to community resources such as the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) and the Supplemental Nutrition Assistance Program (SNAP, formerly food stamps) must be facilitated. Pediatricians should be prepared to advocate vigorously for patients in need of supplemental nutrition or special infant formulas when families experience difficulties in obtaining these products.

### Severe Undernutrition

Children who are less than 60% of ideal body weight for height should be hospitalized, as should any less severely undernourished child who fails to respond to appropriate outpatient management with adequate weight gain. They should be cared for by a multidisciplinary team of nutritionists, social workers, pediatricians, and pediatric subspecialists, with attention to avoiding the refeeding syndrome with its attendant morbidity. The nutritional rehabilitation of these children will be more prolonged and may entail a period of tube feedings in addition to oral supplements. In cases in which the gastrointestinal tract is temporarily inaccessible, parenteral feedings with central venous access may be necessary. The laboratory evaluation of these patients will also need to be more intensive, with appropriate surveillance of potential electrolyte disturbances that can accompany initial refeeding if it is pursued too aggressively.

### Follow-up

Once identified, poor weight gain in infancy should be followed up assiduously. Initial weekly visits for infants may be necessary to reassure the parents and physician that the therapy undertaken is having the

desired effects. Studies of hospitalized children demonstrate that those younger than 6 months, when provided with adequate calories, begin to gain weight in a few days. Older children may take longer than their younger counterparts before sustained weight gain is established. Ongoing developmental, behavioral, and social evaluations must be incorporated into any plan for follow-up. Abnormalities in these domains need to be monitored closely because they are frequently present in patients who gain weight poorly. Moreover, the lingering effects of calorie, protein, and micronutrient deprivation may show themselves in developmental and behavioral abnormalities, particularly in families in which the mothers exhibit affective disorders.

### PROGNOSIS

Outcomes for children who have abnormal weight gain patterns in infancy and childhood should be predicted cautiously in view of the variety of conditions that may give rise to this clinical picture and the lack of high quality data on which reasonable predictions might be sustained. A systematic review of 13 long-term longitudinal studies of children with failure to thrive lamented these methodologic challenges but concluded that the growth and neurocognitive outcomes in these children probably do not differ substantially from their unaffected peers. A less sanguine view was taken by an extensive review of the literature conducted by the Agency for Healthcare Research and Quality, which concluded that children with failure to thrive in infancy are likely to suffer immunologic, behavioral, cognitive, and psychomotor developmental deficits that persist despite interventions. Such disparate findings suggest that most children in the mild category will experience brisk nutritional rehabilitation and, with adequate follow-up, will do quite well. More severely affected children, depending on the cause of their condition, may require more prolonged or repetitive interventions and may be left with residual cognitive, behavioral, and educational consequences of their malnutrition. There is some evidence that intense interventions, including weekly home visitation programs, can, at least in controlled circumstances, attenuate the anthropometric deficiencies that might otherwise result from

significant undernutrition in infancy. In light of these findings, all children who exhibit faltering weight gain during infancy and childhood absolutely must receive early comprehensive evaluation and prompt treatment.

### WHEN TO REFER

- Diagnosis is made of a chronic disease pertaining to a subspecialty such as cardiology, pulmonary medicine, nephrology, gastroenterology, or endocrinology
- Psychosocial family dynamic indicates a need for psychiatric intervention for either or both parents
- Nutritional rehabilitation warrants the attention of a nutritionist
- Provider is concerned about intentional starvation or neglect, a referral to Child Protective Services must be made

### WHEN TO ADMIT

- Any child with a weight less than 60% of ideal body weight
- Any child who, despite appropriate outpatient management, continues to fail to gain weight at an acceptable rate
- Any child who presents with signs of marasmus or severe protein malnutrition (kwashiorkor)
- Any child for whom the provider believes a period of close, continuous monitoring would be helpful

## Chapter 150 FAMILY DYSFUNCTION

Mary Iftner Dobbins, MD; Sandra Vicari, PhD, LCPC

## INTRODUCTION

Theories of child development have long recognized that children in modern Western cultures require approximately 2 decades of life to achieve the self-sufficiency necessary for separation from their families. Because of this relatively prolonged dependency and because adverse childhood experiences negatively affect the developing brain and long-term health outcomes, the functioning of the family is of utmost importance for optimal development and well-being of the child.

Complex sociocultural changes continue to redefine the family, with fewer “traditional” households that historically have consisted of 2 married biologic parents located near extended family members for support. Single, divorced, remarried, same-gender, foster, and adoptive parents are commonplace. Children may also experience multiple, changing parental figures if grandparents assume their care or if biologic parents move on to new partners. Many children have half-, step-, or foster siblings. Particularly in times of economic hardship, families may move in together or experience frequent changes in composition.

In the case of separation or divorce, children often live between 2 different households. Children may also be separated from a caregiver for prolonged periods because of parental employment, illness, or incarceration. The mobility of Western society has resulted in the geographic isolation of many nuclear families from extended family support. Oftentimes, nonrelatives assume the roles of extended family members.

Many children have a family that changes dramatically over time. As a result, family may be defined less by composition and more by functional relationships. In fact, the American Academy of Family Physicians (AAFP) states, “The family is a group of individuals with a continuing legal, genetic and/or emotional relationship.” The AAFP additionally asserts, “Society

relies on the family group to provide for the economic and protective needs of individuals, especially children and the elderly.” When children are involved, the most important function of the family is to provide a safe and caring environment in which the child can grow and develop into a healthy adult.

## FAMILY CHARACTERISTICS

Families function in complex and multifaceted ways, with family members tending to assume various roles that interplay. Changes in the functioning of an individual member affect the family unit, and changes in the family unit affect the individual members and their interactive roles. As a result, a variety of internal and external factors may influence the functioning of a family, and some families are more adaptable and resilient than others.

Healthy families have well-defined roles (ie, parent or child). Members freely ask for and provide attention, but boundaries are respected. Rules tend to be explicit and remain consistent, but with some flexibility to adapt to the individual. Communication is encouraged, and emotional expression is accepted. Security in relationships allows individuals to explore their own interests, and individuation is encouraged. As individual members grow and develop, the family as a unit adapts, also experiencing ongoing intrinsic growth and development over time, which is a sign of health.

All families experience misunderstandings, conflicts, and stressors at some time. Stressors may be internal (eg, illness, change in composition) or external (eg, financial insecurity, relocation). Healthy families cope with difficulties and maintain a sense of connectedness, which fosters a sense of security, self-worth, and competence in their children.

## PARENT CHARACTERISTICS

For the child, the most critical characteristic of a healthy family is an adult who functions as caregiver. In fact, the most important contributory factor regarding children’s resilience is the presence in their lives of at least 1 consistent, caring adult. This adult not only addresses safety and basic needs, but also shares an emotional connection with the child, conveying the sense that she has intrinsic value and is loved.

When 2 (or more) caregivers are involved, the relationship between them is exceptionally important. A supportive and flexible partnership fosters good parenting. Even those with very different backgrounds, knowledge, and attitudes can provide a consistent and united approach without undermining each other.

Specific parental practices do not have to be perfect. Although some are more intuitive than others, people with a variety of abilities, personal backgrounds, and personality types can be good parents. However, there are certain characteristics of maturity that are necessary for optimal caregiving—the ability to care for oneself, a sense of self-worth, the ability to emotionally connect with another person, a sense of responsibility, and a degree of selflessness. Healthy parents do not desire a child to fix something in their own lives or relationships.

Parenting styles depend on many factors, including the parent’s emotional health, experience in their own family of origin, and experience in the parental role, as well as the influence of or compromise with other adults assuming a co-parenting role, culture, and socioeconomic factors. Some traits are more enduring, but parenting styles may be dynamic because of these changeable influences. The needs and temperament of a particular child may also result in variations in parenting. Conversely, children may vary in their response to parenting styles because of their developmental stage, temperament, and degree of resilience.

A parent who can maintain a healthy caregiver role helps the child develop a sense of self-worth and competence, learn to maintain appropriate interpersonal relationships, and plan for her independent future.

## Effects of Parenting Styles

Certain parenting styles are characteristic of healthy families. A caring yet authoritative parent will be attentive to the child and responsive to his needs, yet set consistent and developmentally appropriate expectations. Emphasis is placed on the parent-child relationship and communication, and discipline is provided in a constructive fashion that fosters the child’s learning and self-control. Growing up in a context of guided yet growing autonomy, these children demonstrate more academic mastery, social and moral maturity, self-regulation, and sense of self-worth as they reach adulthood.

Conversely, some parenting styles may have less favorable outcomes. Authoritarian parents satisfy their own need for control by granting little autonomy while also remaining less interpersonally involved with the child. Expectations for behavior give poor consideration to the needs or developmental abilities of the child, who learns over time that approval and affection may be conditional and unpredictable. Consequently, these children typically have poor self-esteem, are withdrawn and anxious, lack in resourcefulness, and are easily frustrated. They reach adulthood with much less mastery, and often exhibit dependent or aggressive behaviors as adults. Not only are these children at high risk for maltreatment, but they are also at high risk for perpetuating the cycle of maltreatment when they have children of their own.

Alternatively, parents may relinquish their authoritative parental role if they are distracted by their own needs or insecure in their parent-child relationship. The resultant permissiveness, whether arising through inattentiveness or overindulgence, grants the child developmentally inappropriate autonomy, adversely affecting their ability to delay gratification and work to meet their own needs. These children enter adulthood with less academic and interpersonal mastery, resulting in less self-control and more demanding and disruptive social behavior.

Parents may also be relatively uninvolved, either from their own emotional detachment or from being overwhelmed by the stressors of their own lives. In the extreme form, this may present as true neglect, and the child may have developmental delays in a variety of areas, including interpersonal attachment. Growing up with little support or discipline, these

children often reach adulthood with little emotional, academic, or interpersonal mastery, demonstrating poor self-esteem and antisocial behaviors.

## **FAMILY DYSFUNCTION**

Difficult life circumstances may stress family functioning. If these circumstances are short-lived or less severe, healthier families adjust and persevere in their developmental tasks. When families become overwhelmed, composition is unstable, individual members are emotionally unhealthy, roles and boundaries are blurred, or communication is impaired, families may function in variations of chronically maladaptive patterns. When a parent figure fails to maintain a healthy parent role, the child's emotional health and development suffer, with potentially lifelong consequences.

Dysfunction can be subtle or severe. However, consequences of these problems affect almost all aspects of a child's life, including relationships, emotions, behavior, learning, the acquisition of coping skills, and psychological development. Instead of developing a sense of self-worth and competence, the child incorporates self-doubt and insecurity. The child has difficulty developing trust and the balanced give-and-take of healthy relationships. In severe cases, chronic disappointment and frustration lead to hopelessness and limited expectations for the future.

## **PATTERNS OF DYSFUNCTION**

Parental dysfunction typically exists in certain core areas. The parent who lacks the desire or ability to emotionally connect with and appreciate the child causes the child to feel devalued and unlovable, undermining the development of healthy attachment. The insecure parent may be overcontrolling in an effort to demonstrate his or her authority, be permissive in an attempt to ensure the child's love, prioritize a partner over caring for the child, or use the child to meet her own needs. The parent who cannot consistently care for him/herself cannot consistently care for the child, resulting in the child's feeling insecure and frustrated. In severe cases, the roles may become reversed, with the child becoming parentified. These characteristics may manifest themselves in many circumstances, but are especially predictable in certain patterns.

### **Uninvolved Parent**

The uninvolved or "inaccessible" parent may be preoccupied with his career, relationships, or community status. As our culture continues to change, even very committed parents may fall into routines that allow less time for their children. They may become caregivers for their own parents or seek new educational or employment opportunities. Families may easily become overscheduled, being "together" disproportionately in a social context rather than as a family unit. In addition, technology frequently replaces, rather than enhances, true interpersonal interaction and communication.

### **Over-involved Parent**

Conversely, parents may become over-involved for multiple reasons. Commonly, parents attempt to

relieve their own youth through their children's activities and status, and may allow little individuation or have unhealthy expectations. Additionally, societal factors have resulted in an extreme focus on achievement, and many children grow up in a culture of extreme competition. Even the possibility of failure may be perceived as an unbearable threat to self-worth, despite the fact that optimal development depends on the child's learning by trial and error. Less secure parents may become overprotective and try to lessen either the risks or the consequences for their children. As a result, the child tends to become less self-reliant, have unrealistically entitled expectations for life independent of the family, blame others rather than learn personal responsibility, paradoxically develop a decreased sense of competency, and consider self-worth to be conditional rather than intrinsic.

### **Divided Loyalties**

When power struggles exist in the family, the child may be put in the middle of the conflict. This is especially true in cases of divorce, in which the parents or extended family members may harbor a great deal of unresolved hurt and animosity. The child, now especially vulnerable and insecure as the family restructures, may be considered a trophy, used as a conduit of information, or forced to choose sides. Children tend to blame themselves for the parents' divorce, and often learn to consider love and relationships as conditional. Frequently, they live with unresolved grief. If parents cannot model appropriate conflict resolution, children often become bullies or victims of bullying.

### **Blurred Roles or Boundaries**

If a parent becomes vulnerable (ie, from illness, addiction, financial insecurity, loss of a relationship, or interpersonal violence), the child also becomes vulnerable. Not only has the child lost a degree of support, but the child often takes on a degree of worry about the parent. If stigma is associated with parental impairment (ie, addiction or mental illness), the child may receive little information or guidance to deal with their confusion, fear, and shame over the parent's circumstances. Many children are unable to develop close relationships because of feelings of loneliness and helplessness.

Blurred parent-child roles or boundaries may occur in a variety of circumstances. When a parent is significantly impaired or when a child loses a parent through death or divorce, the child may become parentified, taking on tasks, concerns, and family roles more appropriately associated with an adult caregiver. This typically results in a tremendous amount of stress and can interfere with his or her developmental tasks.

## **PRESENTATIONS IN THE PRIMARY CARE SETTING**

Physicians caring for children should be mindful of family functioning as it affects the well-being of the children both physically and emotionally. This is

especially true in the setting of the medical home, where a physician with an ongoing relationship with the child and family coordinates continuity of care. The American Academy of Pediatrics (AAP) Task Force on Mental Health has recommended that children's health supervision visits routinely include psychosocial screening of the family, as well as the child. However, any encounter provides an opportunity for assessment and intervention as indicated.

Family dysfunction may present in a wide variety of ways in the primary care setting. The appropriateness of physical care is typically more obvious, as the physician assesses safety, growth and development, general health, and medical care. The family who has trouble keeping appointments or completing treatment may be showing signs that the parent is overwhelmed or that there are other barriers to care.

The child in a struggling family often develops signs of stress, which may manifest physically (eg, frequent somatic complaints) or emotionally (eg, mood or behavior changes). Changes in sleep, appetite, energy, motivation, self-care, school achievement, recreational pursuits, or social interactions are cause for some degree of further exploration. Often, parents are unaware of the child's internal distress until external behavior problems (eg, irritability, aggression, school failure, drug use, self-injury) arise.

When family disturbance is severe, maltreatment may occur. Pediatricians and other physicians receive formal training in the detection of child abuse and neglect, and are uniformly considered to be mandated reporters for child welfare agencies. However, families (including the victim) often conceal abuse or neglect, necessitating a high index of suspicion. Chronic maltreatment, especially sexual abuse, may only be detected by specific investigation.

The growing tendency of families to use emergency departments and urgent care centers in addition to (or instead of) a medical home setting (or even the practice of seeing more than 1 physician within a clinic) undermines continuity of care, and may also mask the degree of dysfunction. The use of multiple physicians should alert the physician to increase vigilance. Appropriate documentation is vital, and forms for release of information facilitate communication among treating physicians.

## THE PHYSICIAN'S ROLE

Family dynamics are complicated, and patterns of interaction can become quite ingrained. However, support for families can have a profound, positive, and enduring effect for children and those in their lives. For the primary care physician, attention to family functioning is inextricably linked to practice, providing many opportunities for supporting the development of healthy families as well as for addressing problems as they may arise.

Indeed, the physician-family relationship provides a unique opportunity for positive influence. Families are built on relationships, and the physician supports the family by first developing a therapeutic alliance with the child and caregiver. In this important position, the physician affirms intrinsic dignity and

self-worth by modeling healthy, respectful interactions with each.

The preventive aspect of primary care integrates routine anticipatory guidance. This helps parents understand their children, guides them through appropriate caregiving practices, and promotes healthy aspects of family development. Over time, the physician gains understanding of differences in personalities, expectations, and the culture of parenting within the family. This allows further customization of care, with recognition of strengths and anticipation of needed support.

In addition to office visits, most physicians provide supplemental educational material and refer families to parenting classes as available. Some physicians incorporate group checkups or classes of their own to facilitate discussion, involve extended family members, and engender parent-to-parent support. When family problems are apparent, the physician may build on the above practices, remaining constructive and supportive.

The timing of well-child visits correlates with the transitional challenges of various developmental stages. Additional visits may be indicated for circumstances that challenge family members, such as the occurrence of night terrors or the experience of divorce. An up-to-date social history is invaluable.

The physician who is sensitive to parental development may prevent problems that arise from misinterpretation ("My baby cries because he doesn't like me"), unrealistic expectations ("He should be toilet-trained by now"), parental self-doubt ("I feel so guilty going back to work"), discipline ("He just needs a good spanking"), and cultural issues ("My father thinks we spoil her").

The need for anticipatory guidance remains dynamic, even as the child matures and seems to be more self-sufficient. Each child is unique, and may challenge a parent in ways a sibling did not. A new parental influence or attitude may be introduced (such as through a remarriage/new partner, more contact with a grandparent, or a new child care or classroom setting). Misinterpretation by a caregiver may become quite problematic (even to the point of maltreatment) if a child is labeled "oppositional," "bossy," "mean," "moody," or "lazy," especially if there is little consideration of the factors that may overwhelm the child and keep him from successfully adapting to the demands of his daily tasks. What seems to be "nothing" to an adult may mean much more to a child.

Many factors that influence parenting behavior may not be readily apparent, even to the parents themselves. A particular age or situation may present a special challenge to a parent who similarly struggled (ie, a mother who was assaulted, or a father who became overdependent on athletic competition for a sense of self-worth).

Typically, family roles are learned in the family of origin. However, rapid cultural changes may result in much different family structures, needs, dynamics, and practices. Commonly, struggles within the family of origin resurface when the now grown child begins a family of her own. Even in the best of circumstances,

there is some degree of differing opinion in regard to parental practices. Clearly, the physician who monitors family development and provides appropriate intervention provides a tremendous support to parental efficacy, child development and sense of self-worth, and overall family health.

For any clinical encounter, the interpersonal interaction is of great importance. However, it is even more so for a family that is struggling. The physician may be among the few consistent supports for the family. Although families typically place trust in the physician who cares for their child, this should not be taken for granted. In fact, there are many cultural stereotypes (ie, industry influence, overuse of medications) that may cause a family to be wary of their physician or treatment recommendations. One should always listen carefully to what the family is truly communicating and confirm shared understanding of the purpose of the visit.

Even if the child is the family member considered to need help, parents may be quite frustrated or ashamed of their perceived failure, and subsequently quite sensitive to any implied criticism. The physician should remain nonjudgmental, acknowledging the parents' care for their child and expressing the desire to problem-solve with them. The physician can both model respectful interactions and constructively guide interactions between family members during the office presentation.

Typically, several techniques are employed. Emotional effect is acknowledged. ("That must have been quite upsetting.") Expectations are clarified. ("We won't use that type of language.") Communication is fostered. ("I feel that we pay attention to each other better if the cell phone is put away.") Positive actions are encouraged. ("I like the way that you followed through with the consequences.") Education is provided.

It is important to have the appropriate family members present and to ensure that each has a chance to be heard. Even if the physician disagrees with a statement or considers an emotion to be unwarranted, it is important to acknowledge an understanding of the perspective being communicated. Disagreement between any participants should be made transparent, with the goal of seeking a common point of agreement upon which to proceed. Problem-solving should be as concrete, achievable, and action-centered as possible. The "next steps" should be agreed upon and documented as specifically as possible ("We will turn off the computer an hour before bedtime.") It is important to acknowledge family strengths, efforts, and successes.

Physician-family interaction may range from a longer, prescheduled, and defined "family meeting" to a few minutes of conversation during a well-child or an acute-care visit. If the allotted time does not seem to be sufficient to the task, this should be acknowledged, with agreement on the acute priority of the day. In this fashion, the physician can accommodate a variety of methods to work with families while still working within the schedule constraints of a clinical practice. By the end of a particular encounter, however, one

should always try to understand the situation as clearly as is feasible, ensure safety, have an agreed-upon plan for the "next steps," and have scheduled follow-up.

Physicians vary a great deal in regard to personality, style of practice, experience, training, abilities, and motivation to work with families. This is especially true when working in challenging situations. Many already feel overtaxed by time constraints, documentation, and other work-related demands. Subsequently, it can be quite daunting to address additional levels of complexity when working with patients and their families. However, techniques can be customized across a variety of practice settings, presenting situations, and professional skill levels.

It is critical for the physician to understand, define, and communicate their own role. Caregivers by nature, physicians may have varied emotional responses to the patients and families in their care. Although families can be a source of joy, they may also engender sadness or other emotions that may not be as transparent. Professionals may feel frustrated with families who do not facilitate care or who challenge their skill level. They may feel anxious in sensitive or disagreeable situations, or feel dislike or anger towards certain patients or family members. They may be even more vulnerable to distress or countertransference in circumstances that resonate with their own life experiences. Often, the needs of the family seem insurmountable or can only be met with resources far outside of the physician's scope of practice. Subsequently, the effective physician needs a certain degree of self-reflection to provide insight into her own emotions and behaviors, and must acknowledge tendencies for minimization or avoidance, maintain appropriate boundaries, develop reasonable expectations for her work, and determine the need for additional resources and support.

As adult learners, physicians monitor their own "practice gaps" and seek information accordingly. A variety of resources is available to enhance the knowledge and skills that facilitate working with families. In addition to the traditional written resources, organizational toolkits, workshops, and mentoring opportunities support the incorporation of knowledge and skills into clinical practice.

Physicians will be most effective if they also use educational and community resources for both children and the adults. There are many books, support groups, and Internet resources for common problems (eg, divorce, bereavement, alcoholism, violence). Families with significant and chronic dysfunction will typically benefit from the specific ongoing guidance of family therapy, and the physician should be aware of local mental health resources. When referral to additional physicians is warranted, personal attention to family engagement will greatly facilitate follow-through with the recommendation.

The AAP Task Force on Mental Health has recommended that physicians develop "common factors" communication skills to elicit an accurate understanding, identify and address any barriers to the care and

follow-up of identified problems, and build a therapeutic alliance with the child and family. Such skills have been shown to be readily acquired by experienced physicians and effective across a wide range of psychosocial problems presenting commonly in the primary care setting.

## CONCLUSION

Family dynamics are complex and vulnerable to a variety of influences. Pediatric practice, however, provides a unique and powerful opportunity to guide not only the development of healthy children, but the development of healthy families as well. By understanding both adaptive and maladaptive patterns of behavior, the primary care physician can prevent problems, detect issues as they emerge, and intervene at early stages. By honing communication skills, using professional resources, and identifying community services, the physician can offer support, provide appropriate materials, and coordinate referrals for more specialized care. This results in profound benefits for children and their families, with the potential to affect generations to come.

## Chapter 151

# FATIGUE AND WEAKNESS

Philip O. Ozuah, MD, PhD; Marina Reznik, MD, MS

## DEFINITIONS

Fatigue and weakness are ubiquitous complaints that may or may not be related to medical diagnoses but are used commonly in medical and colloquial language. Both terms are difficult to define. To add to the confusion, both patients and physicians often use the 2 concepts interchangeably. Moreover, adolescents and children often use other terms to describe their perceptions of somatic weakness and fatigue. Fatigue, in fact, is very different from true body weakness. Therefore, defining the 2 terms carefully is important, although the definitions must be modified for each age group.

*Fatigue* involves extreme and unusual tiredness, decreased physical performance, and an excessive need for rest. It often is accompanied by feelings of sleepiness, weariness, irritability, lassitude, boredom, and decreased efficiency. *Weakness*, in contrast, refers to diminished body or muscle strength, either the inability to generate force or maintain force (stamina), or both. True weakness can be identified only by demonstration of abnormal neurologic or muscular function based on history, physical examination, or laboratory techniques. Practically speaking, a history of weakness, on further questioning, will often suggest hypotonia in infants and will be expressed in older children as trouble running or keeping up in gym class, clumsiness, or lack of agility.

## ETIOLOGY

### Fatigue

Fatigue may be a normal result of any physical or mental work in which energy expenditure exceeds the restorative processes. The temporary fatigue that follows intense exercise involves several complex mechanisms, including increased central inhibition mediated by group III and IV muscle afferents along with a decrease in muscle spindle facilitation and suboptimal cortical output. At the level of the muscle cell, fatigue results from a reduction in adenosine triphosphate caused by high utilization rates, as well as a depletion of glycogen. Normal fatigue also follows activities such as cramming for examinations and occurs with food or sleep deprivation. In all of these instances, the degree of fatigue, even when prolonged, is usually appropriate for the amount of physical or mental exertion expended.

On the other hand, fatigue may be a pathologic state with an organic or psychological foundation. The lassitude associated with somatic illness, often with definable physical or laboratory abnormalities, is well known. Fatigue has also been shown to have a strong correlation with the psychiatric diagnoses of depression and anxiety disorder. Any acute illness or trauma

may be accompanied by fatigue, but only prolonged fatigue is usually noteworthy.

### Weakness

True weakness in a child should always be a cause of concern. Weakness is the result of a derangement of neuromuscular function at one of several levels, including the cerebral hemispheres, cerebellum, spinal cord, anterior horn cells, peripheral nerves, myoneuronal junction, or muscle.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of prolonged fatigue is listed in Box 151-1. Box 151-2 lists some of the differential diagnoses for weakness in children.

### Fatigue in Infants

The term *fatigue* is rarely pertinent for infants. However, parents sometimes report that their infant tires easily during feedings or seems droopy. Infants who are in heart failure often appear to tire easily and sweat excessively with feedings. Infants who have other serious conditions, including severe anemia and hypothyroidism, may also be described by their parents as being listless.

### Fatigue During Childhood

Children complain only infrequently of feeling fatigued. Remarkably, even with chronic organic diseases, the child does not express fatigue itself verbally. Rather, concerned parents usually report that the child appears fatigued. Parents commonly make such statements as, "He has no energy," "She lies around all the time," "She seems bored and droopy," "He's sleeping a lot of the time," "She has no pep," "He drags around," or "I can't get her to do a thing." On questioning, younger children occasionally express a sense of lassitude and fatigue to their pediatrician. Much of the difficulty in the middle years of childhood (before adolescence), however, is children's inability to put into words what they feel. Fatigue, therefore, is usually exhibited in terms of a child's physical activity and performance in school, sports, and other organized activities. The younger the child, the more likely that the expressed or observed fatigue has a pathologic basis.

### Recurrent or Chronic Infection

The most common problem associated with fatigue in children is recurrent or chronic infection. Otitis media, sinusitis, and tonsillitis of a recurrent and smoldering nature are often overlooked for their systemic effects, among which fatigue may be prominent. Often mistakenly considered insignificant, upper respiratory tract allergies may cause impressive fatigue, irritability, and mild depression in children and adolescents.

### Endocrine Disorders

Of the common endocrine disorders, only hypothyroidism is likely to be associated with fatigue. Certainly, a child with hypothyroidism whose rate of growth has fallen off may exhibit increasing fatigue and lassitude, at first subtle, as the only symptoms. Thyrotoxicosis, in contrast, is uncommon in young

## BOX 151-1 Disorders Commonly Associated With Prolonged Fatigue in Different Age Groups

### INFANCY

- Cyanotic heart disease
- Congestive heart disease
- Severe anemia
- Hypothyroidism

### CHILDHOOD

- Chronic upper respiratory tract infections
- Otitis media and sinusitis
- Tonsillitis
- Chronic asthma
- Chronic allergies
- Hepatitis
- Rheumatic fever
- Disseminated malignancy
- AIDS
- Immunologic disorders
- Chronic renal disease
- Obstructive sleep apnea

### ADOLESCENCE

- *Mycoplasma* and other viral pneumonia
- Infectious mononucleosis
- Hepatitis
- Juvenile idiopathic arthritis
- Systemic lupus erythematosus
- Diabetes mellitus types 1 and 2
- Malignancy
- Inflammatory bowel disease
- Addison disease
- Drug abuse, including alcoholism
- Chronic pulmonary disease
- Juvenile primary fibromyalgia
- Obstructive sleep apnea
- Narcolepsy
- Depression
- Severe obesity

## BOX 151-2 Differential Diagnosis of Weakness and Hypotonia

- Down syndrome
- Spinal muscular atrophy
- Muscular dystrophies
- Congenital hypothyroidism
- Botulism
- Myasthenia gravis
- Guillain-Barré syndrome
- Juvenile dermatomyositis
- Polymyositis

children but occasionally produces isolated fatigue in adolescents.

### Diabetes Mellitus

Although any metabolic disorder can cause fatigue, only diabetes mellitus occurs with enough frequency

to merit consideration. Fatigue almost always accompanies the initial or uncontrolled diabetic state.

### **Inflammatory Diseases**

Inflammatory diseases, especially juvenile idiopathic arthritis and other rheumatologic disorders, appear frequently in pediatric practice, and many children have significant fatigue, out of proportion to their musculoskeletal complaints. Lyme arthritis is a notable example.

### **Pulmonary Disease**

Cyanotic heart disease and chronic advanced pulmonary disease, as seen with cystic fibrosis, are commonly associated with marked fatigue; in these cases, however, the underlying disease is usually readily evident before the fatigue becomes severe. The pediatrician may occasionally see an older child for the first time who has severe fatigue caused by a previously undiagnosed hypoxic disorder.

### **Anemia**

Overall, the condition thought to be present most often as a cause of fatigue in both children and adults is anemia—usually, incorrectly so. Although fatigue is often ascribed to mild or moderate anemia, from whatever source, symptoms are usually not seen in children until the hemoglobin level falls to 6 or 7 g/dL; if red blood cell counts decrease gradually, then even lower hemoglobin levels may ensue without clinically evident symptoms. Irritability and attention problems may be present with mild to moderate iron deficiency anemia, but fatigue is usually not a common feature. Younger children especially seem to tolerate incredibly low hemoglobin levels with no symptoms at all.

### **Malignancy**

Malignancy, particularly leukemia or lymphoma, occasionally develops insidiously, with fatigue as the major symptom. Although always feared, these diseases are seen infrequently in pediatric office practice.

### **Emotional Disorders**

Many children who come to the pediatrician with unexplained chronic fatigue are found to have an emotionally related disorder. Before adolescence, the complaint usually centers on the parents' concern about a child's reduced activity level. A younger child will be noted to prefer sedentary activities—to "lie around the house a lot," appear tired, lack energy, and shrink from social contacts. These traits may have been longstanding, but a comment from grandparents or a teacher may arouse parental anxiety, precipitating the first visit to the pediatrician.

At this point, the family is often convinced that the child has a serious organic disease. Further evaluation, however, usually reveals that the child is performing very satisfactorily but not up to the family's excessive expectations. The child may be withdrawing because of failure to compete with an exceptional sibling or because of real or imagined failure in school. In other cases, a child may feel a lack of well-being because of parental discord. Similarly, lack of parental

involvement with a child may lead to lassitude and boredom. Stress and anxiety in children often result in either hyperactivity or withdrawal, and the more common withdrawal reaction may express itself as chronic fatigue.

Most children experience transient periods of lassitude or fatigue, but such instances are brief and usually self-limited. At the opposite extreme is the child whose chronic fatigue is a sign of true psychiatric depression. In this case, as in the adolescent, the more protracted and severe the periods of withdrawal, the more likely that depression and fatigue are caused by a pathologic process.

### **Fatigue in Adolescents**

Complaints of chronic fatigue are encountered most often in adolescents. The normal swings in adolescent moods, from excessive exuberance to fatigue, are usually of more concern to parents and teachers than they are to the patient. In many instances, the adolescent may disagree vehemently with the parents' view and not share their concern. Adolescents, however, also initiate visits to their pediatrician because they feel fatigue. Parents may be unable or may refuse to recognize the adolescent's symptoms. Whereas a younger child who has a profound medical illness often does not experience fatigue, even minor illnesses often precipitate prolonged fatigue in adolescents.

### **Viral Illnesses**

*Mycoplasma pneumoniae* infection, often low grade and without fever, produces progressive fatigue. In addition, prolonged viral and parasitic illnesses (eg, infectious mononucleosis, hepatitis, cytomegalovirus infection, toxoplasmosis) commonly produce fatigue, especially in adolescents.

### **Infectious Mononucleosis**

The terms *chronic infectious mononucleosis* and *chronic fatigue syndrome* have become popular with both physicians and the media. This attention has led to misuse of these terms, as well as, undoubtedly, mild mass hysteria among young adults and adolescents who now are convinced they have one of these disorders. Most adults and many infants and children have been infected with the Epstein-Barr virus (EBV). The clinical manifestations in proved cases are extremely variable; some patients remain symptom free, whereas clinical, hematologic, and serologic findings support the diagnosis of infectious mononucleosis in others. The symptoms of infectious mononucleosis usually resolve in several weeks, but an occasional patient may have an atypical or a more prolonged course in which the initial clinical findings either persist or are intermittent over a period of months or, in rare cases, years. These unusual but documented cases of chronic infectious mononucleosis typically include complaints of chronic fatigue. Another much smaller group of patients has been described as having a serious, sometimes lethal, illness associated with EBV infection. These patients usually do not exhibit the classic findings of infectious mononucleosis; their conditions are often proved to be either acquired or genetically determined immunologic abnormalities.

### Other Conditions

Always unpredictable and often insidious in its onset, inflammatory bowel disease may arouse concern initially with unexplained fatigue and a loss of sense of well-being. Although eventually accompanied by fever, abdominal symptoms, or abnormal stools, this disorder can continue for months, with fatigue as the only major symptom. The possibility of Addison disease should be considered in children or adolescents who have unexplained fatigue and associated weakness, anorexia, nausea, vomiting, or weight loss. Of more current importance in older children and adolescents are alcoholism and drug abuse—causes of chronic fatigue that are easily overlooked.

### Emotional Disorders

By far, adolescents are the patients who most commonly complain of fatigue. Pediatricians can expect to see a generous number of adolescents who characteristically appear each spring complaining of fatigue or lassitude and lack of energy and seem mildly depressed. This disorder usually appears during periods of greatest school-related stress, such as before examinations. Although the patient may have a fever, usually caused by infection (eg, infectious mononucleosis, influenza), the cause of fatigue is usually emotionally based.

In many instances, the adolescent collapses with fatigue after intense and exuberant activity involving schoolwork, extracurricular activity, sports, or social events. These individuals may also be short on sleep, have unhealthy eating habits, and complain of an additional variety of hypochondriacal symptoms. Burnout and fatigue are particularly common in overachieving high school and college students during late adolescence. The emotional reaction may actually be precipitated by a physical illness, particularly an infection. Most of these patients have normal findings on physical examinations and routine laboratory tests.

### Chronic Fatigue Syndrome

Since 1985, adolescents, adults, and, occasionally, children have been described as having a disorder referred to as *chronic fatigue syndrome* (CFS), which most commonly involves persistent or relapsing severe fatigue, fever, headache, sore throat, tender lymphadenitis, nausea or vomiting, myalgia, arthralgia, and abdominal pain. Neurocognitive complaints, such as an inability to concentrate, sleep disturbances, episodic confusion and memory problems, depression, anxiety, and irritability, are also especially common in CFS.

The neurocognitive complaints are the most difficult to evaluate in CFS because of the extreme difference in emotional perception from person to person. Furthermore, careful physical examinations by experienced physicians often fail to document any physical abnormalities, and extensive laboratory evaluations usually produce normal results. In addition, much of the difficulty surrounding both the diagnosis and the search for a cause of CFS is attributable to confusion about the use of the terms *chronic fatigue* and *chronic fatigue syndrome*. Consequently, in 1994, the Centers for Disease Control and Prevention (CDC) formulated

strict criteria for the case definition of CFS. Unfortunately, these criteria were based mainly on observations of adult populations and may not be completely pertinent to children and adolescents.

Nevertheless, the CDC criteria for CFS stipulate that the debilitating fatigue must last at least 6 months in addition to the presence of 4 or more symptoms (such as muscle pain, tender lymphadenopathy, headaches, arthralgia, pharyngitis, impaired memory or concentration, low-grade fever, postexertional malaise, and sleep disturbances). Although the CDC criteria exclude most past or current major psychiatric disorders, they allow some comorbid psychiatric symptoms, such as anxiety and nonmelancholic depression. This allowance can be problematic because both anxiety and depression have an independent and well-established relationship with fatigue.

Chronic fatigue syndrome quickly became a popular diagnosis. The syndrome was initially attributed to infection with the EBV, although few patients had documented physical findings or hematologic abnormalities consistent with the diagnosis of infectious mononucleosis. In addition, most patients had no serologic evidence of active EBV infection. Recently, however, a better understanding of the natural course of EBV antibody activity in healthy individuals months and years after an initial illness with infectious mononucleosis indicates that healthy patients who had mononucleosis years earlier could not be differentiated from fatigued patients who currently had the disease.

Until recently, the diagnosis of CFS in children and adolescents was based on adult criteria. However, children with the illness may exhibit a different symptomatology than adults with CFS. In 2006, the International Association of Chronic Fatigue Syndrome published a Myalgic Encephalomyelitis/Chronic Fatigue Syndrome (ME/CFS) Pediatric Case Definition. The main difference from the adult diagnostic criteria for CFS is a 3-month requirement for fatigue and other symptoms. Although few longitudinal data are available, the prognosis for pediatric patients with CFS is better than that for adults. Although symptoms may persist for months or several years, most children and adolescents with CFS have a good outcome, with approximately one-half reporting complete recovery.

### Weakness

Infants with weakness are often brought to their pediatrician with a complaint of being floppy. A floppy infant is usually one who has hypotonia caused by a neuromuscular disorder. (See Chapter 167, Hypotonia.) In the newborn period, some of these patients may assume a *frog-leg* position. Chromosomal anomalies such as Down syndrome, congenital hypothyroidism, and the infantile form of spinal muscular atrophy (Werdnig-Hoffmann disease) are some of the more common causes of hypotonia in infancy. Infant botulism from ingesting *Clostridium botulinum* spores in honey can cause infants to appear floppy with a weak cry caused by muscle weakness, loss of head control, lethargy, inability to feed, and constipation.

Older children and adolescents who have weakness experience difficulty walking, running, and participating in athletic activities. Myasthenia gravis and

Guillain-Barré syndrome (postinfectious polyneuropathy) are perhaps the 2 most common causes of weakness in this age group. A distinguishing clinical feature is that, in myasthenia gravis, deep tendon reflexes may be diminished but are rarely absent, whereas Guillain-Barré syndrome is remarkable for bilateral, symmetrically absent tendon stretch reflexes. Other causes of weakness in the older child include the muscular dystrophies, the juvenile form of spinal muscular atrophy, dermatomyositis, and polymyositis.

## EVALUATION

### Relevant History

Although the patient who is chronically fatigued may first appear to have an insignificant problem, great care must be taken to rule out underlying medical illness, to return the child to a state of well-being, and to relieve parental concerns. The pediatrician must remember that either the child or the parents are worried about the child's fatigue. Because family members may disagree about the significance of the symptoms, adequate time and concern are needed to evaluate the history. The symptoms of chronic fatigue cannot be dismissed casually over the telephone or with a quick office visit.

Because most patients who come to the physician complaining of fatigue have emotionally based problems, a careful history, with information from both child and parents (taken separately when appropriate), often helps narrow the differential diagnosis. An accurate assessment of sleep patterns, presence or absence of snoring, nocturnal awakenings, and daily exercise activities is essential. Discrepancies between the child's and the parents' observations soon become evident, and the diagnosis of emotionally related fatigue emerges in most cases based on the history alone. The information derived from a longstanding physician-patient relationship contributes enormously to reducing tensions during the evaluation. Although fatigue may be the only symptom, further questioning almost always uncovers other symptoms of somatic disease. Chronic fatigue, in the absence of other physical symptoms, is usually emotionally based. Other associated complaints are somnolence, depression, anxiety, boredom, decreased activity, and inappropriate affect. In many instances, emotional stress or some disruption in the patient's life is part of the history.

### Physical Examination

A physical examination, thoroughly performed, may be the only measure necessary and may reassure the anxious child or parent. The child's affect and appearance are most revealing. The impression that the child appears well invariably proves to be an accurate measure of the child's health. The condition of the adolescent, in contrast, may be more difficult to interpret. Although the physical examination may be benign, adolescents may be slovenly, uncommunicative, depressed, and unable to express their feelings; thus, at first, adolescents sometimes appear to be physically ill.

In all age groups, a search should be made for sites of chronic latent infection: adenopathy, enlargement

or tenderness of the liver and spleen, and abdominal masses. Careful palpation for an enlarged or tender thyroid gland is essential. Mild scleral icterus and petechiae are easy to overlook. Similarly, a patient's pallor (a common finding, especially after long winters indoors) may evade even the most experienced physician. On the other hand, the characteristic facies of the chronically allergic child and signs such as clubbing and cyanosis are obvious. Examination of the oropharynx may reveal hyperpigmentation of gums and buccal mucosa, which may be present in Addison disease.

An assessment of the plotted height and weight should be an essential part of every routine health visit. Failure of a child to progress along the expected growth parameters should draw the physician's attention to the possibility of an underlying systemic process affecting growth and causing unexplained fatigue. A normal linear growth velocity decreases the possibility of chronic cardiac, pulmonary, gastrointestinal, or renal disorders in children or adolescents who are excessively tired. An underlying endocrinopathy, such as hypothyroidism or Cushing syndrome, may cause fatigue in association with poor growth velocity and obesity. Poor weight gain over time may be a subtle manifestation of inflammatory bowel disease in adolescents with unexplained fatigue.

### Laboratory Testing and Imaging

A limited, well-selected group of laboratory tests should be performed on most patients who are chronically fatigued. These results will reassure the family, the patient, and the pediatrician and will usually erase any lingering doubt about the diagnosis.

### Other Diagnostic Tests

The laboratory evaluation should initially include a complete blood count with red blood cell indices, thyroid and liver function tests, a throat culture, and a stool examination for blood. The cold agglutinin test is often valuable as a simple initial screening test for a *Mycoplasma* species infection. Radiograms are rarely necessary and should be discouraged. Critical evaluation of data collected from the history, physical examination, and laboratory tests should enable the physician to detect quickly any organic causes of fatigue. Prolonged fever, however low grade, must always be viewed as significant and may suggest infection, inflammatory disease, or malignancy. Pallor points to the possibility of anemia or hypothyroidism. Hypertrophied tonsils or snoring and disturbed sleep might direct investigation toward a sleep study to evaluate airway competence during sleep and motor activity during sleep, and toward electroencephalogram tracings. In adolescence, a multiple sleep latency study may be considered in teens with fatigue and somnolence for early detection of narcolepsy.

### Viral Disease

Cervical adenopathy, even a single enlarged node in the absence of other findings, can be a clue to the diagnosis of infectious mononucleosis. In fact, in the autumn and early winter of each year, every physician begins to look for patients who have infectious mononucleosis.

However, infectious mononucleosis is a protean illness, and the physical examination results are sometimes normal. Children and adolescents who have infectious mononucleosis may have no fever or signs of toxicity but may exhibit major fatigue. Furthermore, results of the heterophile antibody test for infectious mononucleosis may be negative in many young children and infants and in approximately 10% of older children and adolescents who have the disease. The reliability of EBV antibody testing has improved to the point at which the diagnosis of acute, active infectious mononucleosis can be confirmed. During the evaluation of chronic fatigue, EBV antibody titers can usually differentiate long-past infection from recent and active infection, thus eliminating EBV infection and infectious mononucleosis as causes for the fatigue and permitting a search for other likely neuropsychiatric causes. Toxoplasmosis and cytomegalovirus infections may mimic mononucleosis closely; these infections produce significant fatigue but with only minimal cervical adenopathy and fever. Positive results of a fluorescent antibody test for toxoplasmosis or cytomegalovirus with negative results of a heterophile antibody test will confirm the diagnosis. Similarly, fatigued children may have hepatitis and may be anicteric (or only slightly icteric), with little or no hepatic tenderness or enlargement. Other common viral infections, especially during convalescence, can cause a prolonged fatigue syndrome accompanied by depression.

### **Chronic Fatigue Syndrome**

The diagnosis of CFS should be restricted to patients who meet ME/CFS pediatric case definition criteria, including the new onset of persistent or relapsing fatigue lasting at least 3 months with no prior history of such fatigue and the exclusion of other clinical conditions that might produce similar symptoms. In addition, the children must have the concurrent occurrence of the classic ME/CFS symptoms, which must have persisted or recurred in the past 3 months of illness (symptoms may predate the reported onset of fatigue).

### **Autoimmune Disease**

Children who have an autoimmune disease may have fatigue with little else at first. Mild articular or periarticular inflammation may be missed on examination. The emphasis must be on careful observation of subtle or minimal physical findings because children usually do not display fulminant findings initially. Children with inflammatory bowel disease, arthritis, or an arthritis-like illness, and some patients with a malignancy (monocytic leukemia, in particular), may have especially prolonged symptoms, including fatigue, without any physical findings whatsoever.

### **Thyroid Disease**

An enlarged, tender thyroid gland and fatigue may indicate thyroiditis with emerging hypothyroidism. However, the thyroid is often palpable and full in healthy adolescents. In any event, chronic fatigue from thyroid disease can usually be ruled out quickly with a thyroid-stimulating hormone and free thyroxine (free T<sub>4</sub>) tests. Some patients who have hypothyroidism

also demonstrate mild to moderate anemia, and those who have active thyroiditis may have an elevated sedimentation rate.

### **Anemia**

To be acceptable as an explanation for fatigue, the diagnosis of pure anemia requires marked reduction of hemoglobin. Red blood cell indices and a reticulocyte count will characterize the anemia and the probable cause. Anemia accompanied by thrombocytopenia, however, suggests leukemia or aplastic anemia. The white blood cell count may be normal in infectious mononucleosis or hepatitis, but lymphocytosis with atypical lymphocytes will most likely be present in the former. The heterophile antibody screening test (the *mono test*) is diagnostic in most such circumstances.

### **Screening and Other Diagnostic Tests**

The erythrocyte sedimentation rate is the most valuable screening test for inflammatory diseases of all varieties. A normal sedimentation rate is usually reassuring in ruling out autoimmune disease, inflammatory bowel disease, chronic smoldering infections, and disseminated malignancies. An elevated sedimentation rate requires further investigation. A routine urinalysis almost always reveals diabetes, and most patients who have chronic renal failure have abnormal urinalyses, as well as significant anemia. In these patients, the subsequent measurement of blood glucose in diabetes and of creatinine or blood urea nitrogen in renal disease can confirm these diagnoses. Hyperkalemia, hyponatremia, and hypoglycemia are useful diagnostic features of Addison disease, with the adrenocorticotrophic hormone stimulation test being the most definitive diagnostic test.

### **Weakness**

The evaluation of a patient who has weakness may include chromosomal studies, muscle enzyme assays, nerve conduction studies, electromyography, edrophonium (Tensilon) challenge, muscle biopsy, and a lumbar puncture, depending on the suspected diagnosis. Consultation with a pediatric neurologist is often required.

## **MANAGEMENT**

After significant organic disease is ruled out in most patients, further management requires meaningful communication among the pediatrician, the patient, and the parents. In younger children, the variability in performance and behavior of healthy children must be put into perspective. Again, appropriate parental expectations must be emphasized. In addition, the child's and the family's daily schedule should be reviewed. A chaotic lifestyle that is frantic, with poorly structured activity and inadequate sleep patterns, is often revealed. Occasionally, true psychiatric depression is discovered, which calls for referral to a psychiatrist.

Older children and adolescents benefit from personal, warm attention. The value of a continuous relationship with a single physician becomes self-evident. An understanding, thorough session with the patient's

pediatrician usually streamlines the evaluation and eliminates the need for excessive testing. Conversation after the physical examination should attempt to reassure children or adolescents about their basic health, reiterate the common and normal occurrence of fatigue, examine the daily routine and stresses on patients, and suggest modifications of patients' lifestyle and approaches to life's situations. This period is a time for respectful give and take. Attempting to establish the probable cause of the fatigue is the physician's responsibility before the patient is referred to a specialist. If emotional fatigue is thought to exist, then the adolescent, in particular, must be comfortable with the conclusion that organic diseases were ruled out. The patient then must be made aware of the emotional basis for the fatigue; if psychiatric referral is needed, then the reasons must be made clear. A knowledgeable pediatrician will be reassuring but firm in approaching the child or adolescent who needs referral. Fortunately, such a referral usually is not necessary.

### WHEN TO REFER

- Unexplained weight loss
- Hypotonia in infants
- Suspected major affective disorder
- Suspected malignancy

### WHEN TO ADMIT

- Severe depression or suicidal ideation
- Need for evaluation of neuromuscular disorders such as spinal muscular atrophy, Guillain-Barré syndrome, and myasthenia gravis

## Chapter 152 FEVER

Élise W. van der Jagt, MD, MPH

For centuries, fever has been associated with illness. As many as 30% of all patients seen by primary care physicians and more than 5 million emergency department visits each year have fever as their principal complaint, making it among the most common reasons children are taken to a physician. Add to this the numerous telephone calls about fever that physicians receive day and night, and it becomes evident that the proper evaluation and management of fever is a basic and necessary skill for everyone caring for children.

Even though physicians have long dealt with this common clinical sign, its mechanism, meaning, and management have remained sufficiently unclear and controversial that research on these matters continues. Although advances in neurochemistry and neurophysiology have improved the understanding of the pathophysiology of fever, clinical investigators continue to search for practical knowledge that will enhance the care of the febrile patient. Availability of such information can simplify the challenging role of the physician, who must evaluate a child quickly and effectively, arrive at a diagnosis, institute appropriate therapy, and both educate and support the parents and child during the entire process. The extent to which physicians accomplish these goals depends on their knowledge of the mechanisms of disease, the various clinical manifestations of disease, and their awareness of the social context in which the disease occurs.

## DEFINITION

The word *fever* is derived from the Latin *fovere*, meaning *to warm*, and commonly means an increase in body temperature. Although this general definition is acceptable in common parlance, fever is described more accurately as an adaptive response of thermoregulation. It must be differentiated from hyperthermia, an increased body temperature resulting from conditions that overwhelm the normal process of thermoregulation.

Normal rectal body temperature ranges between 97°F and 100°F (36.1°C and 37.8°C), although, on rare

occasions, it may be as low as 95.5°F (35.3°C) or as high as 101°F (38.3°C). The *normal* temperature of 98.6°F (37°C) was derived from an 1868 study of more than 1 million axillary temperatures taken in adults. This value may have no relevance for children, not only because adults were studied, but also because axillary and rectal temperatures correlate poorly. Young children seem to have higher body temperatures than adults, with temperatures slightly higher than 37.8°C occurring commonly in those younger than 2 years. The upper limits of the normal range for a rectal temperature are 100.4°F (38°C) for newborns younger than 1 month, 100.6°F (38.1°C) in 1-month-olds, and 100.8°F (38.2°C) in 2-month-olds. A total of 6.5% of well infants less than 3 months old have been reported to have rectal temperature of 100.4°F (38°C). Nevertheless, because it is unknown which of these infants have these relatively high “normal” temperatures, it is safest to consider 100.4°F (38°C) as an abnormal temperature (fever) in this age group. Lowest body temperatures occur between 2 am and 6 am, and the highest ones occur between 5 pm and 7 pm, a diurnal variation that persists even during a febrile illness.

Because a range of normal body temperatures exists, it may be helpful in some instances to know a child’s usual body temperature so that an abnormal increase can be recognized more easily. The extent to which body temperature is increased above normal may help determine the presence and significance of fever. This circumstance may be true especially in young infants, in whom even a mild fever may be associated with serious disease. Although the variability and range of normal temperatures in children have made it difficult to define fever precisely and consistently, a consensus panel of experts has recommended that the lower limit of fever be defined as a rectal temperature of 100.4°F (38°C). This definition has become standard and is used both clinically and in research studies about fever.

## SIGNS AND SYMPTOMS ASSOCIATED WITH FEVER

The behavior of humans and animals is remarkably similar when fever is present. When the set point in the hypothalamus is increased, patients attempt to adjust the environment to keep their bodies at this higher temperature. Young children usually seek close contact with a warm person (generally a parent), wish to be covered by a blanket, sit near a warm stove or register, and refuse cold liquids or foods. Although children may be quite comfortable at this higher body temperature, they interact less with others, have a decreased ability to concentrate, substitute quieter activities for energetic ones, and become less communicative except to indicate discomfort and distress. This adaptive withdrawal is often accompanied by loss of appetite and complaint of headache.

Such a combination of behavioral symptoms is a familiar indicator of illness to most parents and usually results first in placing the hand on the forehead, then measuring the temperature with a thermometer.

Unfortunately, parents may not recognize the onset of fever in the younger child because the alterations in behavior are fewer and subtler. In a small infant, irritability and loss of appetite may be the sole evidence of fever and disease. If a parent is not familiar with these subtle cues, then recognition of serious illness may be significantly delayed.

In addition to the behavioral changes that may accompany fever, the general physical examination may reveal a pronounced hypermetabolic state. The child may have flushed cheeks, have an unusual sparkle in the eyes (likely from pupillary dilatation), and be either sleepy and lethargic or exceptionally alert and excited (particularly 5- to 10-year-olds). With rare exception, the pulse is increased by approximately 10 to 15 beats per 1°C of fever, and the respiratory rate is increased. (If the pulse rate is less than expected for the degree of fever, then typhoid fever, tularemia, mycoplasma infection, or factitious fever should be considered.) The skin may feel hot and dry (“burning up with fever”), although the distal extremities may be cold and pale (vasoconstricted), obscuring an extremely high core body temperature. Most children are not particularly uncomfortable, but some may shiver or sweat, mechanisms by which the body increases or decreases temperature. Sweating may be so severe that dehydration occurs, particularly if the intake of fluids has been poor. Thus, a dry mouth and lips may result not only from rapid mouth breathing, but also from dehydration. Finally, irritability of the central nervous system may increase, resulting in a febrile seizure.

The aforementioned signs and symptoms may be less obvious in a small infant. Shivering does not occur in the first few months of life, and diaphoresis is seen less often than in the older child. Because irritability and pallor may be the only suggestions of illness, a careful measurement of the temperature should be taken if the parent mentions these signs.

## PRESENTATION

A febrile child may come to the attention of a primary care physician in several ways. Probably the most dramatic and frightening manifestation of fever in a child is the sudden occurrence of a seizure. A generalized tonic or tonic-clonic seizure, usually lasting less than 15 minutes and occurring within 24 hours of the onset of fever, may begin without warning. Most parents are not aware that a fever is present and often feel guilty for not having noted it. The primary care physician may be called immediately after the seizure has occurred or after the child has been transported to the emergency room. There the child is likely to be postictal and have a rectal temperature of 102°F to 104°F (39°C–40°C). A thorough assessment of the patient is indicated because a seizure may be the first sign of meningitis or encephalitis.

Although some experts have suggested that every patient who has a first febrile seizure should routinely undergo a lumbar puncture (LP), the American Academy of Pediatrics (AAP) recommends an approach that takes the age and immunization status of the child into consideration. The younger the child is, the more difficult it is to diagnose meningitis clinically

(eg, meningismus, Kernig sign, Brudzinski sign), and strong consideration should be given to performing an LP. In infants younger than 6 months, an LP should be strongly considered because clinical signs of meningitis may be absent. In children between 6 and 12 months of age, when clinical manifestations of meningitis still may be subtle, an LP should be considered if the infant has not received the recommended immunizations for *Haemophilus influenzae* and *Streptococcus pneumoniae* or immunization status is unknown. Infants who have received the 3 *H influenzae* and *S pneumoniae* immunizations are unlikely to develop meningitis from these organisms. In children older than 12 months, an LP is not routinely warranted except in the presence of signs and symptoms suggestive of meningitis or other intracranial infection. Because antibiotic treatment can mask meningitis, an LP should also be considered in a child with a fever and a seizure who has received antibiotics. Reexamination of the child after the convulsive episode may also help determine whether an examination of the cerebrospinal fluid is needed.

More commonly, a patient with fever is first examined when the fever has been present for longer than 24 hours and is associated either with nonspecific symptoms or with symptoms referable to a particular organ system. Inasmuch as many evaluations of febrile children take place over the telephone (the first contact with the physician), the physician must be able to take an accurate and pertinent history. Of particular significance are the age of the patient (the younger the child is, the more thorough the evaluation will need to be), any associated signs and symptoms, exposure to illness in the family or community, history of recent immunizations, and a history of any recurrent infections (eg, urinary tract infections [UTIs], streptococcal infections, otitis media). The time of year also should be considered, because certain viral illnesses are more prevalent at particular times of the year. For example, respiratory syncytial virus (RSV) and influenza virus infections are more common during the winter, parainfluenza virus infections (the most common cause of croup) are more common during the spring and especially in the fall, and enterovirus infections occur primarily during the summer. In addition, questions should be asked about the duration and height of the fever. A low-grade fever that has been present for many days usually does not need to be evaluated as urgently as a temperature of 106°F (41°C) that has been present for a few hours. The former is more likely to indicate a chronic or benign illness; the latter is more likely to be a potentially rapidly progressive infectious disease. Unfortunately, the height of the fever is often not very reliable in distinguishing viral from bacterial illness or even serious from nonserious disease. Young infants especially may not have much of a fever or even be hypothermic during a serious infection.

A visit or telephone call for minimal fever and little evidence of disease should prompt a thorough assessment of the psychosocial factors that may be contributing to parental concern. Is the main concern about something else—a hidden agenda? Is the caregiver

anxious about the fever because of lack of knowledge about its significance? Has the caregiver had a previous traumatic experience with disease, resulting in excessive anxiety? Might the patient be a vulnerable child? Is this family dysfunctional, in which minor illness either cannot be dealt with or is used as a means to meet other needs? Answers to these questions and others may clarify the situation.

## DIFFERENTIAL DIAGNOSIS

Because many conditions may cause fever, an extensive discussion about each condition is beyond the scope of this chapter. However, classifying conditions associated with fever into broad categories is useful (see Box 152-1). In addition to specific etiologies, dehydration, excessive muscle activity, autonomic dysfunction, and heat exposure all may cause hyperthermia.

Although any disease in these categories may cause fever at any age, some diseases are more likely to occur at some ages than at others. Autoimmune disease and inflammatory bowel disease, for example, are unusual in infants but become progressively more common with increasing age. Similarly, febrile immunization reactions are much more common during the first year of life when most immunizations are administered.

Infections affecting the respiratory and gastrointestinal tracts account for most fevers in all age groups. Most of these infections have a viral origin (eg, enteroviruses, influenza virus, parainfluenza virus, RSV, adenovirus, rhinovirus, rotavirus) and are generally self-limited. Knowledge of the seasonality of these viruses promotes correct and efficient diagnoses. In addition, knowledge of the typical physical findings in these infections and their course may help distinguish them from bacterial diseases. For example, high fever, irritability, posterior cervical adenopathy, and painful vesicles on the gums and tongue are characteristic of herpes gingivostomatitis. Failure to examine the tongue and gums may result in an unnecessary workup in search of a possible bacterial infection. On the other hand, assuming that a high fever in a 2-month-old infant is from roseola (exanthem subitum) would be erroneous because this

### BOX 152-1 Differential Diagnosis of Fever

- Infection
- Autoimmune disease
- Neoplastic disease
- Metabolic disease (eg, hyperthyroidism)
- Chronic inflammatory disease
- Hematologic disease (eg, sickle cell disease, transfusion reaction)
- Drug fever and immunization reaction
- Poisoning (eg, aspirin, atropine)
- Central nervous system abnormalities
- Factitious fever

infection (human herpesvirus type 6) usually does not occur at such an early age.

## EVALUATION

Failure to evaluate the fever further might result in missing a serious bacterial infection. Although viral infections may cause significant morbidity and mortality, the more aggressive course and serious outcomes of bacterial infections make early diagnosis especially important, particularly because effective antibiotic treatment is usually available. Bacterial infections may be especially devastating in younger children who are relatively immunocompromised because of their immature immune systems. An infection that remains localized in the older child may disseminate rapidly in the infant and toddler, particularly to the blood (bacteremia), the lungs (pneumonia), the meninges (meningitis), the bones (osteomyelitis), and the joints (arthritis). Because these infections may be seriously debilitating or even fatal if not recognized, the physician must be able to differentiate bacterial infections from the more benign viral infections.

At greatest risk are those children who present with fever or hypothermia and have severe sepsis or septic shock, because the mortality, although better than in adults, is still as high as 8% to 12%. These children typically have a constellation of symptoms and signs collectively called systemic inflammatory response syndrome (SIRS), along with evidence of organ dysfunction. The Worldwide Pediatric Surviving Sepsis Campaign has standardized (by consensus of experts) the definitions of SIRS, sepsis, severe sepsis and septic shock as outlined in Table 152-1, Table 152-2, and Table 152-3.

Early recognition and aggressive, goal-directed therapy can decrease mortality significantly. This means that careful clinical and laboratory assessment is necessary to identify patients, give antibiotics within an hour, and provide early and rapid fluid administration (eg, 20 mL/kg boluses of crystalloid given over 5–10 minutes), along with early use of inotropic agents as appropriate to normalize the patient's physiology. Both the International Surviving Sepsis Guidelines for pediatric patients and the American Heart Association's Pediatric Advanced Life Support Sepsis algorithm provide guidance to the management of these patients.

The younger the child is, the more difficult it is to recognize bacterial infection. Complaints cannot be verbalized, and physical signs and symptoms are more subtle and easily missed unless a high index of suspicion is maintained. Serious bacterial disease is especially difficult to diagnose in children with no obvious focus of infection. For this reason, many attempts have been made during the last 30 years to identify children in whom fever is a sign of a serious bacterial infection, particularly pneumococcal disease and infections caused by *Haemophilus influenzae* type b (Hib). Children between birth and 36 months of age have been of special interest because fever is most common in this age group, and they may be difficult to assess, particularly during the first 3 to 6 months of

**Table 152-1** Systemic Inflammatory Response Syndrome Criteria

SIGN	AGE	VALUE
Temperature	All ages	<36°C or >38.5°C
Heart rate (bpm)	0 days–1 mo	<100 or >180
	1 mo–1 yr	<90 or >180
	2–5 yr	>140
	6–12 yr	>130
	13–18 yr	>110
Respiratory rate (rpm)	0 days–1 wk	>50
	1 wk–1 mo	>40
	1 mo–1 yr	>34
	2–5 yr	>22
	6–12 yr	>18
White blood cell count ( $\times 10^3/\text{mm}^3$ )	13–18 yr	>14
	0 days–1 wk	>34
	1 wk–1 mo	>19.5 or <5
	1 mo–1 yr	>17.5 or <5
	2–5 yr	>15.5 or <6
	6–12 yr	>13.5 or <4.5
	13–18 yr	>11 or <4.5
	all ages	>10% bands (immature WBC)

WBC, white blood cell.

From Goldstein B, Giroir B, Randolph A; International Consensus Conference on Pediatric Sepsis. International pediatric sepsis consensus conference: definitions for sepsis and organ dysfunction in pediatrics. *Pediatr Crit Care Med*. 2005;6(1):2–8, with permission from Wolters Kluwer Health.

life. Efforts to improve the ability to diagnose a serious bacterial infection have focused on 3 areas: data from the history and physical examination, laboratory data, and response to antipyretics. Of the 3 areas, the response to antipyretics has been shown most clearly to be unhelpful in distinguishing between patients who have a serious bacterial infection and those who have a more benign viral infection. Children who have a serious infection respond to antipyretics no differently from those whose illness is less significant. In fact, some children who have viral illnesses do not defervesce either.

Many studies have attempted to delineate the precise combination of clinical or laboratory variables that might identify the febrile child at risk for serious disease. Defined clinical observational scales (eg, Yale Observation Scale, Young Infant Observation Scale, Severity Index) are not sufficiently discriminatory and predictive to be used alone. Laboratory studies continue to be necessary as well.

During the early 1990s, specific practice guidelines were published to facilitate the initial management of febrile infants and children without an obvious source of infection. Although these guidelines remain controversial, as many as one-third of primary care physicians found them to be helpful and changed the way they evaluated young children with fever. Nevertheless, each patient continues to require individual assessment, with application of the recommendations as

**Table 152-2** Sepsis-Related Definitions

Systemic inflammatory response syndrome (SIRS)	The presence of at least 2 of the following SIRS criteria, 1 of which must be an abnormal white blood cell (WBC) count or abnormal temperature: (1) temperature abnormality; (2) tachycardia/bradycardia; (3) increased respiratory rate; (4) abnormal WBC count.
Sepsis	SIRS + evidence or suspicion of infection.
Severe sepsis	Sepsis + (cardiovascular dysfunction OR acute respiratory distress syndrome OR 2 other organ dysfunctions [see Table 152-3]).
Septic shock	Severe sepsis + cardiovascular dysfunction as defined in the organ dysfunction.
Refractory shock	<i>Fluid Refractory:</i> Cardiovascular dysfunction persists in spite of >60 mL/kg of fluid over 1 hr. <i>Catecholamine Refractory:</i> Cardiovascular dysfunction persists in spite of >10 mcg/kg/min of dopamine and/or need for epinephrine/norepinephrine.

**Table 152-3** Severe Sepsis—Organ Dysfunctions

Cardiovascular	Despite >40 mL/kg fluid in an hour, there is systolic hypotension OR need for vasoactive drugs to keep BP within normal limits OR 2 of the following: capillary refill >5 sec; unexplained metabolic acidosis (base deficit >5 meq/dL); oliguria (<0.5 mL/kg/hr urine); lactate >2× upper limit of normal; >3 degrees between peripheral and core temperature.
Respiratory	Any of the following: $P_{aO_2}/F_{iO_2}$ <300 in absence of cyanotic heart disease or pre-existing lung disease; >50% $F_{iO_2}$ to maintain $O_2$ sat >92%; $P_{CO_2}$ >65 or >20 mm Hg over baseline; need for nonelective mechanical or noninvasive ventilation.
Neurologic	Glasgow Coma Scale ≤11 or an acute change in Glasgow Coma Scale with decrease of ≥3 from baseline.
Hematologic	Platelets <80,000 or >50% decrease from previous 3-day baseline OR INR >2.
Hepatic	Total bilirubin ≥4 mg/dL OR ALT >2× upper limit of normal.
Renal	Serum creatinine ≥2× upper limit of normal or 2× baseline.

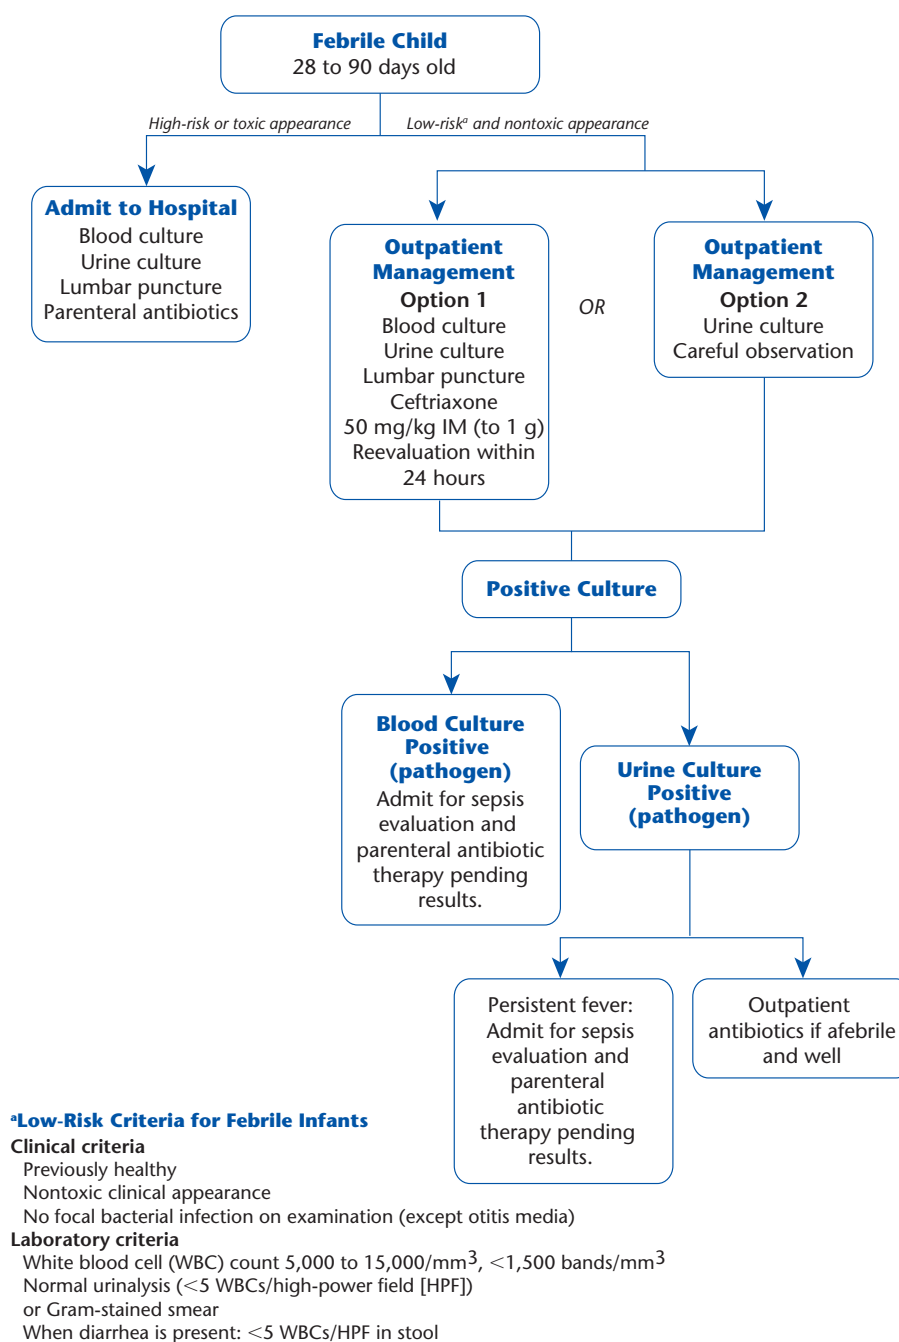

ALT, alanine aminotransferase; BP, blood pressure;  $F_{iO_2}$ , inspired fraction of oxygen; Hg, mercury; INR, international normalization ratio;  $P_{aO_2}$ , partial pressure of oxygen in arterial blood;  $P_{CO_2}$ , partial pressure of carbon dioxide.

appropriate to the individual context of the patient. Considerations of the inconvenience, discomfort, and cost of laboratory testing and the increasing resistance to antibiotics in the community must be weighed carefully against the risk of missing a serious bacterial infection, with its subsequent morbidity and mortality. Therefore, physicians must make the best decisions possible in an environment of incomplete certainty about the presence of serious disease. Parents need to be part of these discussions, and adequate follow-up of all patients is crucial, no matter what is decided in the initial visit.

Although the early practice guidelines were helpful during the 1990s, they were formulated before the introduction in 2001 of the heptavalent pneumococcal vaccine for infants. This vaccine provides protection against pneumococcal serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F, and is administered at 2, 4, and 6 months and between 12 and 15 months of age. With the introduction of the vaccine, a decline of 60% to 80% in pneumococcal disease occurred in children younger than 24 months. In 2010, a more comprehensive pneumococcal vaccine was introduced, covering 13 serotypes including serotype 19A, with similar recommendations for administering it 4 times in the first 15 months. Because occult pneumococcal bacteremia and other pneumococcal

infections made up most of the serious bacterial infections in young children with high fever (>102°F [>39°C]), the use of this vaccine greatly lowered the incidence of serious bacterial infections in children at greatest risk—those between 2 to 3 months and 3 years of age. A similar effect occurred when the Hib vaccine was introduced in the 1980s, nearly eliminating Hib meningitis, epiglottitis, and bacteremia. Given the marked decrease in pneumococcal and Hib serious bacterial infections, the likelihood of a serious bacterial infection when high fever (>102°F [>39°C]) is present in infants and toddlers is now even smaller, and a fairly limited assessment may be more suitable at this time. In addition, with an increased ability to diagnose specific viral illnesses (RSV, influenza, enterovirus) by rapid diagnostic testing with polymerase chain reaction (PCR) methodology, and the increased use of inflammatory markers more typically associated with bacterial infections (procalcitonin, C-reactive protein), the likelihood of missing a serious bacterial infection is even lower. Thus, even the revised, updated practice guidelines of 2000 are no longer as useful as they once were (figures 152-1 and 152-2).

Fever during the first 4 days of life has been associated with a high incidence of bacterial disease. A temperature above 98.6°F (37°C) occurs in 1% of all

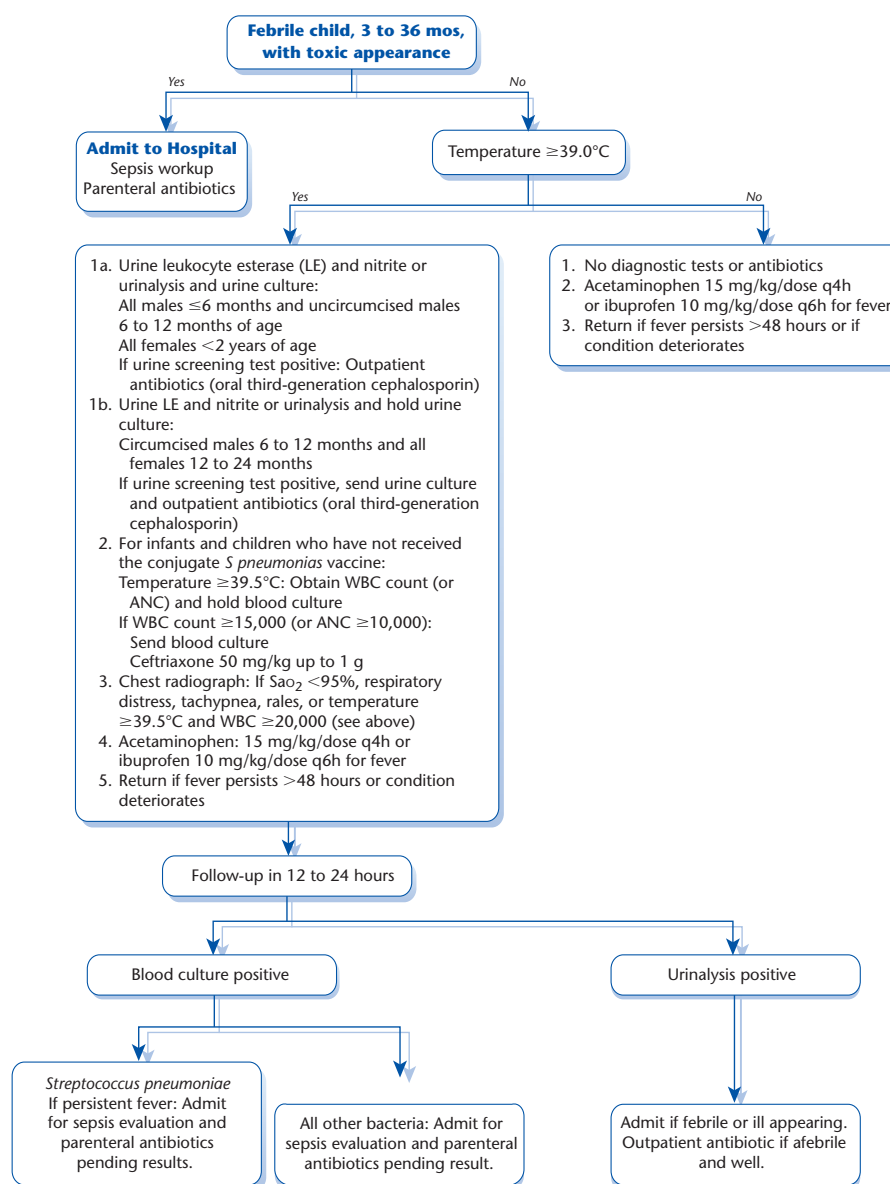

**Figure 152-1** Algorithm for the management of a previously healthy infant 28 to 90 days of age with fever without source at least 100.4°F (38°C). (From Baraff LJ. Management of fever without source in infants and children. Ann Emerg Med. 2000;36:602–614. Copyright © 2000, Elsevier, with permission.)

newborns; of these children, 10% have a bacterial infection, usually caused by group B streptococcal or gram-negative enteric pathogens. A full workup is indicated in these children, including a complete blood count and differential count, a urine analysis, and cultures of the blood, urine, and cerebrospinal fluid (CSF); antibiotics (usually intravenous ampicillin and gentamicin, or ampicillin and cefotaxime) should be administered until the results of cultures are known.

Similarly, neonates up to 28 days of age with fever have a significant risk of a bacterial infection (approximately 12% in some studies). Pneumococcal infection is uncommon; *Escherichia coli* (*E coli*), group B *Streptococcus*, and other enteric pathogens are more usual; *E coli* is by far the most common and *Listeria monocytogenes* has become very uncommon. Urinary tract infection (UTI) and occult bacteremias are the most common types of infection;

**Figure 152-2** Algorithm for the management of a previously healthy child 91 days to 36 months of age with fever without source. (From Baraff LJ. Management of fever without source in infants and children. Ann Emerg Med. 2000;36:602–614. Copyright © 2000, Elsevier, with permission.)

however, with group B *Streptococcus* infection, the risk of accompanying meningitis is as high as 39%. Low-risk criteria, such as the Rochester criteria, may not be consistently reliable to differentiate young patients with serious bacterial infection from those who have more benign disease. Although some studies have demonstrated only a 0.2% incidence of bacteremia or meningitis in neonates satisfying the low-risk criteria, others have found that up to 6% of neonates who satisfy low-risk criteria have a serious bacterial infection. Of note, neonates with RSV infection do not have a lower incidence of serious bacterial infection when they have fever but these are typically UTIs and not meningitis or

bacteremia. Concomitant UTIs are especially common, occurring in 5% to 7% of patients. In addition to bacterial infection, herpes simplex virus (HSV1/HSV2) infection, especially meningoencephalitis, should be considered in any neonate who has risk factors for HSV infection (maternal primary HSV infection, prolonged rupture of membranes, fetal scalp electrode use) or clinical evidence (temperature elevation/depression or instability, seizures, lethargy, skin/oral/ocular vesicles, CSF pleocytosis, or hemorrhage). Acyclovir is the treatment of choice while awaiting an HSV PCR test on spinal fluid/blood/surface cultures to confirm the diagnosis.

Fever of 100.4°F (38°C) or higher in infants between 28 and 60 days of age is associated with a 5% to 10% incidence of serious bacterial infection. Unfortunately, neither height of fever nor apparent degree of toxicity has been a reliable predictor by itself of bacteremia or serious bacterial infection. Instead of using a single predictor, a combination of clinical and laboratory criteria seems to be more useful in identifying infants who are at low risk for having a bacterial infection. The most well known of these combinations are the Rochester criteria (Table 152-4). The infants must satisfy all of the following conditions: previously healthy (as defined in Table 152-4), no clinical signs of toxicity (in some studies defined by an infant observation score of  $\leq 10$ ), no focal bacterial infection found at physical examination, a white blood cell (WBC) count between 5,000 and 15,000 cells/mm<sup>3</sup> with 1,500 bands or fewer, a normal urinalysis ( $\leq 5$  WBCs per high-power field [HPF] with few or no bacteria found in centrifuged urine and a Gram-stained smear of stool demonstrating fewer than 5 WBCs/HPF if diarrhea is present. If cerebrospinal fluid is obtained, then the cell count should be 8 WBCs/HPF or fewer. One- to 2-month-old infants who satisfy these criteria have only a 1.1% probability of having a serious bacterial infection, and a 0.5% probability of having meningitis.

Because of the difficulty in determining solely by the degree of fever whether an infant younger than 3 months is at a low or high risk for bacterial disease (septicemia has occurred even in infants who have low-grade fevers), evaluation should be prompt and thorough whenever a fever of at least 100.4°F (38°C) exists, paying particular attention to obtaining the data necessary for classifying the child as low or high risk. Such a comprehensive evaluation should generally include a complete physical examination, total and differential WBC count, urinalysis and urine culture, a Gram-stained smear of stool if diarrhea is present, blood culture, and possibly examination and culture of cerebrospinal fluid. A urine culture is especially important because UTIs are the most common bacterial infections in this age group, even in the absence of pyuria.

If the infant seems nontoxic and meets the low-risk criteria, then examination and culture of the cerebrospinal fluid and blood might reasonably be avoided as long as good observation and follow-up can be made within 24 hours and antibiotics are not administered. If antibiotics are to be administered, then a full workup, including blood and cerebrospinal fluid cultures, should always be performed.

After obtaining a thorough history, including queries about illness of a similar nature in other family members and queries about whether the child has been immunized with the Hib and pneumococcal vaccines, the physician should assess the child for toxicity. If the child seems toxic (eg, lethargic or irritable, noninteractive, poor perfusion), then hospitalization should be considered along with further diagnostic tests to assess for serious bacterial infection. If the child does not seem toxic, a WBC count should be considered; if this count is greater than 15,000/mm<sup>3</sup>

**Table 152-4**      **Rochester Criteria**

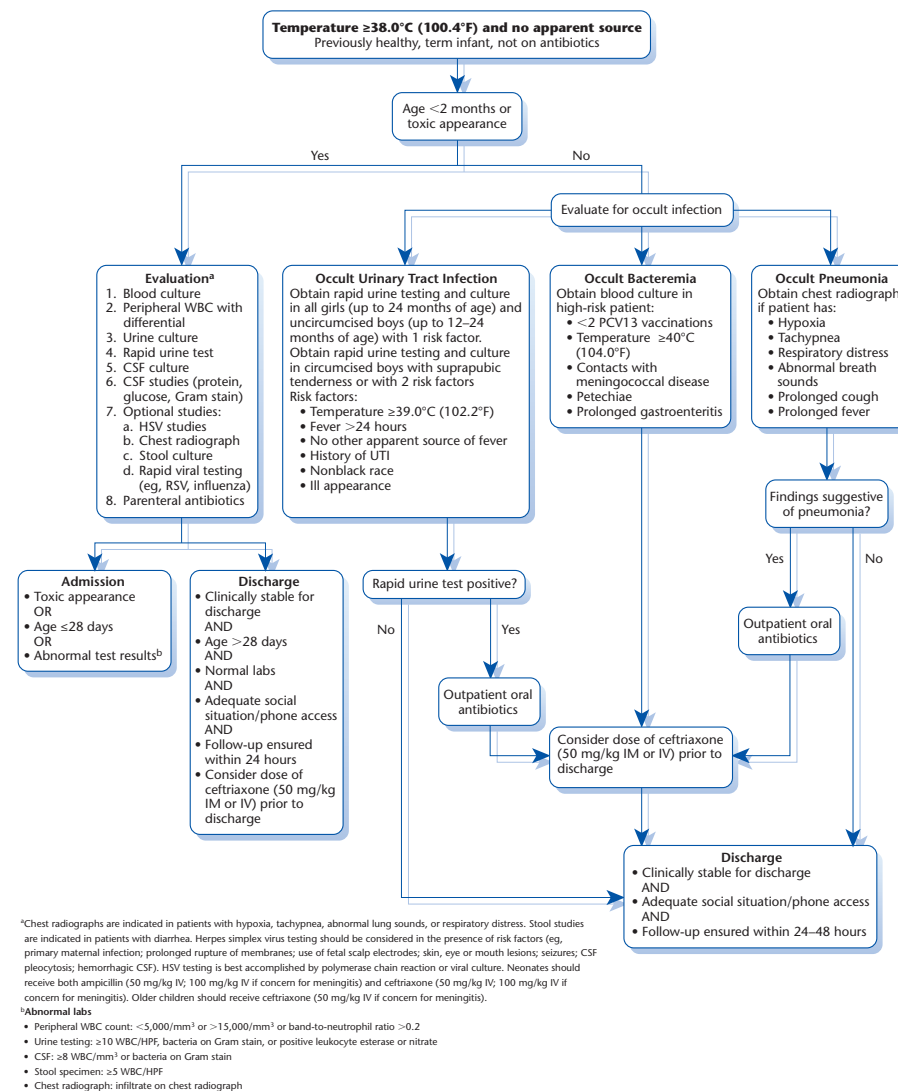

- 1 Infant seems generally well.
- 2 Infant has been previously healthy.  
Born at term ( $\geq 37$  weeks' gestation).  
Did not receive perinatal antimicrobial therapy.  
Was not treated for unexplained hyperbilirubinemia.  
Had not received and was not receiving antimicrobial agents.  
Had not been previously hospitalized.  
Was not hospitalized longer than mother.
- 3 No evidence of skin, soft tissue, bone, joint, or ear infection.
- 4 Laboratory values:  
Peripheral blood white blood cell (WBC) count 5.0 to  $15.0 \times 10^{11}$  cells/L (5,000 to 15,000/mm<sup>3</sup>).  
Absolute band form count  $\leq 1.5 \times 10^{11}$  cells/L ( $\leq 1,500$ /mm<sup>3</sup>).  
 $\leq 10$  WBC per high-power field ( $\times 40$ ) on microscopic examination of a spun urine sediment.  
 $\leq 5$  WBC per high-power field ( $\times 40$ ) on microscopic examination of a stool smear (only for infants with diarrhea).

From Jaskiewicz JA, McCarthy CA, Richardson AC, et al; Febrile Infant Collaborative Study Groups. Febrile infants at low risk for serious bacterial infection—an appraisal of the Rochester criteria and implications for management. *Pediatrics*. 1994;94:390–396.

then a blood culture should be considered. In the pre-pneumococcal vaccine era, children with WBC counts  $>15,000/\text{mm}^3$  were 5 times as likely to experience bacteremia as those who had WBC counts  $<15,000$ . In addition, an absolute neutrophil count of at least 10,000/mm<sup>3</sup> correlated with an increased (8.2%) risk of pneumococcal bacteremia. Practically, obtaining the WBC and blood culture at the same time is easiest, with the blood sent for culture only if the WBC count warrants doing so. Procalcitonin and C-reactive protein blood levels might have better sensitivity and specificity than the WBC count in predicting serious bacterial infection, but findings from various studies still vary widely with respect to the best cutoff levels to use.

Given the lower incidence of pneumococcal disease now, avoiding blood tests altogether might be more cost-effective and reasonable as long as the child has received at least 3 doses of the Hib and pneumococcal vaccines, does not seem toxic, has no obvious focus of infection, and has reliable physicians with excellent follow-up capabilities.

Approximately 5% to 8% of children in the 3- to 36-month-old age group who have an undifferentiated febrile illness have a UTI. Two groups of patients in this age group are especially at risk. Female infants with temperatures greater than 39°C (102.2°F) have a UTI incidence of 16% to 17%. Uncircumcised boys in the first 12 months of life have an 8- to 9-fold higher rate of UTI than circumcised boys. Because of the high rate of UTIs in this age group, a urine culture is suggested for febrile boys younger than 6 months of age. A urinalysis alone is generally not adequate as a screening tool to determine which child should have a

**Figure 152-3** Fever without apparent source in children 0 to 24 months old. (From Ishimine P. Risk stratification and management of the febrile young child. Emerg Med Clin N Am. 2013;31:601–626. Copyright © 2013, Elsevier, with permission.)

urine culture; 20% of children who have a UTI have a normal urinalysis, including a negative test for urinary nitrites or leukocyte esterase. However, a more recent study suggests that the urine dipstick may be an adequate screen for ruling out a UTI, with a negative predictive value of over 98%. A chest radiograph is generally necessary only if clinical symptoms or signs suggest pneumonia (eg, cough, tachypnea, dyspnea, rales, decreased breath sounds, dullness to percussion). However, at least 1 study has suggested that up to 20% of children with fever of at least  $102.2^{\circ}\text{F}$  ( $39^{\circ}\text{C}$ ) and a WBC count of more than  $20,000/\text{mm}^3$  have pneumonia by chest radiograph, even in the absence of respiratory symptoms and signs.

If one considers all of the above, it is obvious that one must attempt to predict the risk of a serious bacterial infection in different age groups and circumstances. The advent of immunizations directed to

serious bacterial pathogens with a subsequent decline in serious illness caused by these agents, and the possibilities of diagnosing viral infection very early, even in the emergency room, make it imperative that a balanced approach be taken in diagnostic testing, hospitalization, and treatment. One way of doing this has been outlined by Ishimine and is shown in Figure 152-3.

A further consideration in the approach to a febrile infant or child in the first 3 years of life is the increased availability of rapid diagnostic viral testing. Rapid tests are now available for influenza A and B, RSV, and enterovirus. Although sensitivity and specificity vary with individual tests, a positive test may be helpful in decreasing the number of other tests that need to be performed to rule out a bacterial infection. Including neonates younger than 28 days, the rate of serious bacterial infections in febrile patients is lower if they

are infected with influenza and RSV. When this rate of infection is coupled with a generally lower incidence of serious pneumococcal and *H influenzae* infections because of the advent of vaccines given at a young age, a reasonable strategy might be to use positive viral tests as a way to reduce blood and urine tests in vaccinated children older than 2 to 3 months who do not seem toxic.

Children older than 3 years are more likely to have signs and symptoms consistent with a recognizable illness. If they have nonspecific symptoms, an urgent consultation with a physician is probably unnecessary; however, regardless of age, all febrile children with localized signs and symptoms, such as swollen joints, meningismus, labored respirations, chest pain, dysuria, petechiae, alteration of consciousness, and severe abdominal pain, should be examined immediately. Moreover, any child with fever or hypothermia who satisfies the criteria for SIRS should be immediately evaluated.

Although many febrile children do not have signs and symptoms pointing to an obvious cause, a complete physical examination may reveal important clues to the origin of the fever. Because most infections involve the respiratory tract, this area must be examined carefully. In all instances, the tympanic membranes should be examined for otitis media, the pharynx for pharyngitis, the nose for the discharge of sinusitis or a viral upper respiratory tract infection, and the lungs for evidence of pneumonia or bronchiolitis. Conjunctivitis may be a clue to adenovirus, influenza or RSV infection, conjunctivitis-otitis syndrome, or Kawasaki disease.

The skin is no less important and may demonstrate typical viral exanthems, such as those associated with rubella, roseola, or chickenpox, or it may show the erythema marginatum of rheumatic fever or the rose spots of typhoid fever.

Generalized lymphadenopathy often occurs with viral illnesses, such as infectious mononucleosis, hepatitis, or cytomegalovirus infection, but it also may be a clue to the diagnosis of leukemia or lymphoma. Localized enlargement of lymph nodes should prompt a search for a skin infection or for a tumor. Isolated cervical lymphadenopathy may be associated with tuberculosis infection or cat scratch disease (*Bartonella* infection).

The musculoskeletal system must be examined with care. Localized bone tenderness may suggest osteomyelitis, and a restricted range of motion in a warm joint may suggest arthritis. Although the latter finding may occur in many different diseases, a meticulous examination of the heart is always indicated to detect the carditis of rheumatic fever or infective endocarditis. The spine should be palpated for any evidence of diskitis, and any costovertebral angle tenderness should prompt an examination of the urine for evidence of a UTI.

Although uncommon, factitious fever is a final consideration and a well-described entity. Children as young as 8 years have been known to increase the thermometer reading artificially by rubbing the mercury thermometer bulb on the sheets or by exposing it to warm liquids. Clues at physical examination include

a pulse that is not correlated with the increase in temperature, inability to document fever when it is measured rectally, and an absence of sweating during defervescence. Investigation of psychosocial disturbances within the family is usually necessary.

## SUMMARY

Although fever may be associated with serious illness, treatment of the fever itself is much less crucial than the evaluation and treatment of the illness causing the fever. Health care professionals are responsible for educating parents about the proper management of their febrile children, emphasizing their role in the observation for signs and symptoms that are more likely to be associated with serious disease. Fever as a harbinger of severe sepsis is especially important and both physicians and parents need to be educated on how to differentiate patients who are septic from those who have a more benign illness. Fever is but a single sign that should be evaluated in the total context of the care of the patient.

## Chapter 153

## FEVER OF UNKNOWN ORIGIN

Élise W. van der Jagt, MD, MPH

Fever without a discernible cause poses several difficulties for the physician. Since fever suggests disease, the inability to identify its cause can create anxiety for the family and the physician, undermine the physician's credibility, and affect patient rapport. The longer the fever persists, the more concerned parents are and the higher their level of anxiety. A fever of only a few days' duration, not associated with any localizing signs or symptoms, usually does not even come to a physician's attention unless the child also appears ill. Fever that continues beyond 5 to 7 days, or that occurs repeatedly, almost always will prompt a medical consultation. This discussion focuses on these prolonged fevers including their evaluation and management.

## DEFINITION

In 1961, Petersdorf proposed the classic definition for a fever of unknown origin (FUO): fever that is higher than 38.3°C (101°F) on several occasions, that is present for more than 3 weeks, and that has a cause that is still unexplained after 1 week of evaluation in the hospital. Since then, researchers have suggested that these criteria are inappropriate for immunocompromised patients and that the third criterion—evaluation—be changed either to reflect the increased emphasis on ambulatory assessment (unexplained fever after 3 days of in-hospital evaluation or 3 ambulatory visits) or to make the evaluation more quantitative by requiring specific tests that should have been performed before applying the label of FUO. The latter definition is more acceptable to most primary care physicians, who usually don't wish to delay evaluation for 3 weeks or require a week of hospitalization. In children, an FUO has been defined as a daily rectal temperature greater than 38.3°C (101°F), lasting for at least 2 weeks, the cause of which has not been determined by simple diagnostic tests, including a complete history and thorough physical examination. Some experts suggest that 1 of the 2 weeks of fever should be documented in the hospital.

Careful and precise documentation of fever is necessary before using the label of FUO. A thorough awareness of the range of normal core body temperature for age, with its diurnal variation, may help to exclude patients who are actually not febrile but, instead, have a high normal body temperature. The physician should teach the parents how to take a rectal temperature and define a day of fever as a 24-hour period in which a temperature greater than 38.3°C (101°F) occurs at least once. All medications taken, the activities in which the child has participated, and the environmental temperature during this time should be recorded because each of these may affect body temperature.

Although much importance has been attached to fever patterns in the past (ie, remittent, intermittent, sustained), detailing them may not be useful because they are rarely diagnostic of a specific disease. Nevertheless, some inflammatory diseases do have recognizable fever patterns (eg, double quotidian fever of systemic idiopathic juvenile arthritis). In addition, it should be carefully determined if even 1 or 2 days of normal temperature have been interspersed between days of fever: children with this pattern may have a series of rapidly sequenced brief febrile illnesses, which are masquerading as a single febrile illness. Careful documentation of fever should also help exclude the so-called *pseudo-FUO* or factitious fever. Children who have a pseudo-FUO not only do not have a true fever if their body temperature is measured accurately and consistently (sometimes this needs to be done under hospital supervision), but also exhibit a specific and recognizable constellation of findings that is often diagnostic (Box 153-1). In addition to the inability to corroborate fever, and in the setting of a completely normal physical examination, the parents may relate a previous serious illness and their concerns about its possible recurrence or lasting effect on the child (vulnerable child syndrome). Their child may have missed an excessive amount of school, given the general degree of illness described; school absence is often prompted by the presence of fatigue, abdominal pain, and headache in the morning—symptoms that are conspicuously absent during the rest of the day. Others have noted a similar pattern of findings and called it *deconditioning syndrome*, which occurs after an acute, easily definable febrile illness and usually occurs in children who are older than 12 years. The syndrome includes significant fatigue, sedentary habits, absence of depression, and a normal neurologic and musculoskeletal exam. Treatment is directed towards

**BOX 153-1 Characteristics of the Child Who Has Pseudo-Fever of Unknown Origin**

- Absence of documented, persistent fever
- Lack of objective, abnormal physical findings
- History of significant or near-fatal illness
- Parental fear of malignant or crippling disease
- Frequent environmental exposure to illness
- Absence of persistent weight loss
- Normal erythrocyte sedimentation rate and platelet count
- Many missed school days because of subjective morning complaints
- Discordance of fever and pulse rate
- Medical or paramedical family background
- One or more of mild self-limited diseases, behavioral problems, parents who have misconceptions concerning health and disease, or families under stress

From Kleiman MB. The complaint of persistent fever. *Pediatr Clin North Am.* 1982;29(1):201–208. Copyright © 1982, Elsevier, with permission.

**BOX 153-2 Causes of Fever of Unknown Origin in Children****INFECTIOUS DISEASES****Bacterial**

- Bacterial endocarditis
- Bartonellosis
- Brucellosis
- Chlamydia
  - Lymphogranuloma venereum
  - Psittacosis
- Dental infections
- Ehrlichiosis
- Leptospirosis
- Liver abscess
- Lyme disease (*Borrelia burgdorferi*)
- Mastoiditis (chronic)
- Osteomyelitis
- Mycoplasma infections
- Pelvic abscess
- Perinephric abscess
- Pyelonephritis
- Salmonellosis
- Sinusitis
- Subdiaphragmatic abscess
- Tuberculosis
- Tularemia

**Viral**

- Cytomegalovirus
- Epstein-Barr virus (infectious mononucleosis)
- Hepatitis viruses
- Human immunodeficiency virus
- Rickettsial diseases
  - Q fever
  - Rocky Mountain spotted fever

**Fungal**

- Blastomycosis (nonpulmonary)
- Histoplasmosis (disseminated)

**Parasitic**

- Malaria
- Toxoplasmosis
- Visceral larva migrans
- Visceral leishmaniasis

**AUTOIMMUNE DISEASES**

- Polyarteritis nodosa
- Sarcoidosis
- Systemic idiopathic juvenile arthritis
- Systemic lupus erythematosus

**MALIGNANCIES**

- Hodgkin disease
- Leukemia
- Lymphoma
- Neuroblastoma
- Pheochromocytoma

**PERIODIC FEVER SYNDROMES**

- Cyclic neutropenia
- Familial Mediterranean fever
- Hyperimmunoglobulinemia D and periodic fever syndrome (HIDS)
- Periodic fever, aphthous stomatitis, pharyngitis, and cervical adenopathy (PFAPA)
- Tumor necrosis factor receptor–associated periodic syndrome (TRAPS)
- Other periodic fever syndromes

**MISCELLANEOUS CAUSES**

- Colitis, granulomatous
- Colitis, ulcerative
- Diabetes insipidus—central
- Diabetes insipidus—nephrogenic
- Drug fever
- Ectodermal dysplasia
- Familial dysautonomia
- Hemophagocytic lymphohistiocytosis
- Infantile cortical hyperostosis
- Kawasaki disease
- Kikuchi-Fujimoto disease
- Münchausen by proxy
- Pancreatitis
- Pseudo-fever (factitious fever)
- Serum sickness
- Thyrotoxicosis

establishing required physical activity in a graduated way while acknowledging that fatigue is present.

Another category of FUO is periodic fever. Instead of a single episode of prolonged fever, affected children have shorter episodes of fever that recur in a regular (periodic) fashion, accompanied by a predictable constellation of symptoms. Patients with this pattern of fever are said to have *periodic fever syndrome*. Many of these periodic fevers are now known to be

genetically based and can be diagnosed by sophisticated genetic testing. Unfortunately, the most common periodic fever (periodic fever, aphthous stomatitis, pharyngitis, and cervical adenopathy [PFAPA]) is not known to be genetic.

**DIFFERENTIAL DIAGNOSIS**

Box 153-2 lists the common causes of FUO in children. The causes are subdivided into 5 main categories:

**Table 153-1** Diagnoses of Prolonged Fever in Children

DIAGNOSIS	AGE		TOTAL
	<6 YEARS	≥6 YEARS	
INFECTION			
Viral	14 (27%)	7 (15%)	21
Nonviral	20 (38%)	11 (23%)	31
OTHER			
Collagen	4 (8%)	16 (33%)	20
Malignancy	4 (8%)	2 (4%)	6
Miscellaneous	7 (13%)	3 (6%)	10
No diagnosis	3 (6%)	9 (19%)	12
Total	52	48	100

From Pizzo PA, Lovejoy FH, Smith DH. Prolonged fever in children: review of 100 cases. *Pediatrics*. 1975;55(4):468–473.

(1) infectious diseases—bacterial/viral/fungal/parasitic, (2) autoimmune diseases, (3) malignancies, (4) periodic fever syndromes, and (5) miscellaneous. This list suggests that most FUOs eventually are found to be caused by common pediatric illnesses that are either self-limited or treatable.

An infectious illness is the most common cause for an FUO in children, comprising between 40% and 60% of the reported cases; the second most common cause is autoimmune disease, comprising between 7% and 20% of the cases. Children younger than 6 years are most likely to have an FUO from an infection; autoimmune diseases become more common after 6 years, although infection remains the most frequent cause of FUO overall (Table 153-1).

Although most infections that present themselves as an FUO are atypical or incomplete manifestations of common infectious diseases, less common infections should also be considered. Epstein-Barr virus is the most common infectious cause of FUO, followed by osteomyelitis and bartonellosis. The advent of serologic testing (indirect immunofluorescent antibodies) for Epstein-Barr virus and *Bartonella* infections has made these diagnoses easier to make. Although bartonellosis (caused by *Bartonella henselae*) usually presents as classic cat-scratch disease, it may also manifest as atypical cat-scratch disease, producing prolonged fever and hepatosplenic abscesses, lymphadenopathy, or central nervous system disease. Thus, when exposure to kittens and cats can be documented, serologic testing for *Bartonella* should be obtained; if positive, an abdominal ultrasound should be considered. Tick-borne diseases should also be considered, especially in areas of the United States where ticks are plentiful. These diseases include Lyme disease, tularemia, tick-borne relapsing fever and ehrlichiosis. Osteomyelitis, particularly of the axial skeleton (intervertebral disk space and vertebral body) and the pelvis, should also be a consideration, especially in young children who are more difficult to examine.

Another interesting syndrome likely initiated by a variety of viruses, and first described in 1972 in adults, is Kikuchi-Fujimoto disease or histiocytic necrotizing lymphadenitis, which is most common in the Far East. Kim recently described a series of 40 children, noting that 90% of them had fever ( $>37.5^{\circ}\text{C}$ ) lasting for a mean of 18 days with tender unilateral cervical lymphadenitis ( $<3$  cm, often multiple). Leukopenia was present in 45%, elevated LDH ( $>500$  U/L) in 88%, and ANA was weakly positive in 30% of patients in whom it was measured. All patients completely recovered.

The appearance during the 1980s and the subsequent increased incidence of HIV infection and acquired immunodeficiency syndrome (AIDS) should encourage primary care physicians to look for characteristic physical signs and symptoms, as well as known risk factors, including parental intravenous drug abuse, parental sexual contact with individuals who may be HIV positive, an HIV-positive mother, and hemophilia requiring transfusion of blood products. Fortunately, in the United States, hemophilia poses less of a risk, since screening for HIV is very sensitive and more synthetic factors are also being used. In addition, infant screening for HIV is also occurring now. Fever is not usually the sole manifestation of HIV infection. However, HIV infection should be strongly considered and the appropriate laboratory tests performed if the fever has been present for more than 2 months and is associated with 1 or more of the following:

- Failure to thrive or a weight loss of more than 10% from baseline
- Hepatomegaly
- Splenomegaly
- Generalized lymphadenopathy (lymph nodes measuring at least 0.5 cm in 2 or more sites, with bilateral site involvement counting as 1 site)
- Parotitis
- Persistent or recurrent diarrhea

Of the autoimmune diseases, systemic-onset juvenile idiopathic arthritis (formerly known as systemic juvenile rheumatoid arthritis) is the most common. Fever is almost always associated with this illness, and it frequently precedes the joint manifestations by weeks or months. The typical double quotidian fever (2 fever spikes in 24 hours with a normal temperature in between) is a helpful clue to this diagnosis. Other common autoimmune diseases that should be considered are lupus erythematosus and chronic regional enteritis. These latter conditions are more common in children older than 6 years.

Malignancy, the diagnosis that provokes the most anxiety, is present in only a small percentage of patients in most studies (1.5%–6%). This is in significant contrast to adults with FUO, of whom between 7% and 16% have a neoplastic process. The most common malignancy in children is leukemia, although solid tumors such as lymphoma, neuroblastoma, hypernephroma, pheochromocytoma and hepatoma have been reported to present as FUO. The exact reason for fever in these diseases is unclear but seems to be related to various endogenous pyrogens such as interleukin-1, interleukin-6 and other cytokines produced by the neoplastic cells. A

large variety of miscellaneous diseases may cause prolonged fevers (see Box 153-2). However, a clear diagnosis is never obtained in 25% to 67% of patients who have persistent fever. These fevers are the genuine FUOs. Most of these patients seem to do well, and the fever eventually disappears after months or even years.

Some patients have fevers that do not satisfy the classic definition of FUO. Instead, they have recurrent fevers that are associated with a well-defined constellation of symptoms each time. The most common of these periodic fever syndromes is PFAPA. This nonhereditary autoinflammatory syndrome has its onset before the age of 3 years, is associated with a sudden fever to 39°C to 40°C (102°F–104°F) lasting 3 to 5 days. Also present are anorexia, mild oral ulcerations with pharyngitis, cervical lymphadenopathy, an increased white blood cell count, and an increased erythrocyte sedimentation rate (ESR). This constellation of symptoms returns every 3 to 6 weeks. A single dose of corticosteroids may quickly resolve the symptoms of individual episodes. In the longest follow-up study available, the average time until resolution of symptoms was 6.3 years, but some patients still had symptoms 18 years later. Removal of adenoids/tonsils has been associated with resolution but it is not always effective.

Other periodic fever syndromes include cyclic neutropenia, familial Mediterranean fever, hyperimmunoglobulinemia D and periodic fever syndrome (HIDS, or mevalonate kinase deficiency), and tumor necrosis factor receptor-associated periodic syndrome (TRAPS). These syndromes are found in various populations around the world and are associated with known gene mutations. The primary care physician should therefore know the patient's race, ethnicity, and country of origin because these factors may provide clues to a specific periodic fever syndrome.

## EVALUATION

### History

Whether the child has a true FUO or a pseudo-FUO cannot be determined without a precise history and thorough physical examination, with the physician paying close attention to behavioral, social, familial, and environmental factors. Information regarding travel, patient residence if outside the United States, animal exposure, frequency of exposure to other persons who have common febrile illnesses, previous illness, hospitalizations, medications, family history of disease, race and ethnicity, and the precise course of the exhibiting symptoms must be obtained methodically and efficiently. Meticulous documentation of dates is especially important. To this end, having the family record on a calendar both the daily time and height of the fever, along with associated symptoms, is usually helpful.

For children older than 11 to 12 years, a separate interview should be conducted alone with the child to obtain the child's perspective on the illness and to elicit information that may be difficult to express in the presence of parents. School, peer relationships, family

functioning, and sexual identity and activity should be explored.

### Physical Examination

A full physical examination must be performed. Rectal temperature, respiratory rate, heart rate, and blood pressure measurements should be obtained. Any discrepancy between heart rate and temperature may imply factitious fever. A thorough examination of the respiratory tract is indicated. Inspection of the tongue and gums for aphthous ulcers, pharynx for hyperemia and exudate, the tympanic membranes for chronic otitis media, and the nose for a purulent nasal discharge, and auscultation of the chest for localized wheezing are all important. In the older child, an examination of the teeth to exclude dental caries and periodontal disease should be included. A new cardiac murmur may be a clue to rheumatic fever or infective endocarditis. A careful abdominal exam may demonstrate an enlarged and/or tender liver, splenomegaly, generalized tenderness, or a mass. Lymphadenopathy, especially if generalized, may suggest a viral infection, such as infectious mononucleosis, cytomegalovirus infection, toxoplasmosis, or HIV infection, but could also suggest leukemia. If lymphadenopathy is limited to the cervical areas, the physician should consider periodic fever syndrome, Kawasaki disease, Kikuchi-Fujimoto disease, and cat-scratch disease. Joints must be examined meticulously for swelling, restricted range of motion, and tenderness. Skin rashes may suggest a viral disease, a tick-borne disease, infectious mononucleosis, or an autoimmune disease such as juvenile idiopathic arthritis. The absence of sweating and the presence of a smooth tongue are consistent with familial dysautonomia, a rare genetic disorder of thermoregulation. Finally, a rectal examination in the older child and a stool guaiac test are imperative; finding pararectal lymphadenopathy may suggest a pelvic infection, and a positive stool guaiac test may be consistent with inflammatory bowel disease.

### Laboratory Evaluation

If the history and physical examination disclose no specific findings and growth is normal, then only simple diagnostic tests are indicated. Routine blood counts and urinalyses have not been shown to be particularly useful, although no one advocates their elimination from the workup. A purified protein derivative tuberculin skin test or interferon-gamma release assay (IGRA) should be done to detect tuberculosis. Negative blood, urine, and throat cultures exclude infections of these areas. One should be careful to recognize that if there is a group A strep positive throat culture without symptoms or physical findings of pharyngitis, one should assume that the throat is colonized with group A strep and this is not the etiology of the fever.

Probably the most useful laboratory tests are the ESR, C-reactive protein (CRP), albumin-globulin ratio, LDH, and uric acid. If the ESR is more than 30, the CRP is elevated, or the albumin-globulin ratio is inverted, then a higher probability of serious disease

exists, particularly an autoimmune vascular disease or a malignancy. Significantly elevated LDH and uric acid suggest tissue breakdown often associated with lymphoproliferative disease or other malignancy. A significantly elevated ferritin is usually present in hemophagocytic lymphohistiocytosis (HLH) and juvenile arthritis with macrophage activation syndrome, but affected children are usually very ill and clearly require hospitalization. Further evaluation should be vigorously pursued.

The remainder of the evaluation should be individualized based on historical and clinical findings. Because infectious causes are the most common, pursuing specific serologic tests for such diseases as hepatitis A and B, Epstein-Barr virus infection (infectious mononucleosis), bartonellosis, toxoplasmosis, and cytomegalovirus infection are reasonable. A radioactive gallium (or other isotope) scan may be useful in detecting occult abscesses and infections, although this scan has been found to be less helpful in children than in adults. Total body computed tomographic scans may help find tumors; however, if the abdomen is of primary concern, an abdominal ultrasound may detect significant abnormalities and would avoid the significant radiation associated with computed tomography. Radiologic studies of the sinuses, the gastrointestinal tract, and the chest all may be appropriate in certain individuals but should not be routine. A bone marrow examination may occasionally help in the diagnosis of tuberculosis, leukemia, metastatic cancer, or fungal infections, but should be considered only in children who have either a clinical or laboratory finding suggestive of malignancy or who are immunocompromised. More recently, with the advent of sophisticated imaging technology, a F-FDG PET or PET/CT scan has been found especially helpful in diagnosing systemic-onset idiopathic juvenile arthritis, obviating further workup. The PET scans demonstrate areas where there is high glucose consumption, typically areas of tumor or inflammation. Further evaluation of the benefit of these types of scans is necessary.

If the ESR, CRP, albumin-globulin ratio, LDH, and uric acid are normal and no signs and symptoms are present that are specific to a particular disease, little can be gained from any of the tests previously mentioned. Observation and periodic evaluation are the only measures that are required while the physician remains alert for the occurrence of new symptoms or signs that might lead the investigation in a specific direction. Fortunately, most FUOs for which a cause cannot be found resolve over time.

Since it is likely that the parents and patient will be anxious about an undiagnosable problem, the primary care physician must be ready to provide all family members with a clear explanation of the evaluative process, any normal results, and reassurance. Referrals to pediatric infectious disease specialists, rheumatologists, specialized diagnosticians, or any combination of these professionals may occasionally be necessary for additional assistance in determining a diagnosis. However, over-referral may accentuate the anxiety of the family.

## SUMMARY

The evaluation of the child who has FUO must be individualized and depends on a careful assessment of the history, the physical examination, and the social context of the child. An initial and often repeated meticulous examination of all these factors is the physician's responsibility and is the first stage of managing the patient. Whether hospitalization is part of this approach ultimately depends on the amount of parental anxiety, the necessity to document fever, and the need for diagnostic tests that cannot be done on an outpatient basis. A minimal number of diagnostic tests is usually sufficient to rule out serious disease that requires aggressive intervention and/or treatment by specific subspecialists.

Frequent assessment of children with persistent FUO is necessary so that subtle clues for diagnoses are not missed, diagnostic testing is timed carefully, and the family continues to maintain confidence in the physician. In the absence of any alarming symptoms, physical findings, or results of diagnostic tests, it is important to emphasize to families and the patient (where appropriate) that even though the fever may last for weeks or months, children with FUOs generally do well.

## WHEN TO ADMIT

Consider admission for the following patients:

- Patients in whom the accuracy of reported temperature is unclear or questionable; temperatures must be taken by hospital staff or under their direct supervision.
- Patients who need multiple tests, many of which require procedural sedation. Coordinating these tests together over a period of 24 to 48 hours may be more efficient than performing them individually as an outpatient.

## Chapter 154

## FOOT AND LEG PROBLEMS

Benjamin Weintraub, MD

## INTRODUCTION

Parents frequently come to the physician with concerns about their children's feet and legs, such as "my son is pigeon-toed," or "my daughter is knock-kneed." In most cases, these findings are purely normal developmental stages seen in the growth of the lower extremities. For example, it is entirely normal for a toddler just starting to walk to be "bowlegged" or "pigeon-toed," or for a 3-year-old to have "knock-knees." However, it may be pathologic for a 10-year-old to have significant genu valgus (knock-knees) or a 5-year-old to have severe genu varum (bowed legs). The physician, then, needs to understand the normal changes seen during growth and development to judge properly when a finding is pathologic and requires further evaluation, treatment, and referral to a specialist.

## NATURAL GROWTH OF LOWER EXTREMITIES

During the course of gestation, the lower extremities of the fetus undergo vast changes. Lower limb buds develop at 4 weeks' gestation. During week 6, the lower limbs begin to flex toward the parasagittal plane, and then proceed to rotate medially so that the knee points cranially and the great toe is brought to the midline. By term, 80% of babies are in the classic fetal position with knees and hips flexed, hips externally rotated, and ankles plantar-flexed and internally rotated. This tightly packaged position conveniently helps drive the femoral head into the acetabulum,

thereby aiding in the development of the hip socket. It also leads to a number of transient conditions that self-resolve over time but until then may cause significant parental anxiety: pigeon toeing and bow legs, or more precisely, internal tibial torsion, metatarsus adductus, and medial femoral anteversion.

Of the remaining 20% not in the usual fetal position, most are in a position with hips and knees flexed, ankles dorsiflexed, and legs and feet externally rotated, which can lead to external tibial torsion, calcaneovalgus feet, and out-toeing.

After birth, the first of these "packaging defects" to self-correct is metatarsus adductus. This medial deviation of the forefoot usually either self-resolves or can be corrected by 1 year of age with simple stretching. Tibial bowing is next to resolve by about age 2 to 4 years. Bowing is usually followed by the appearance of an increasingly knock-kneed or genu valgus stance from 3 to 5 years of age. By the end of the first decade of life, tibial torsion goes from a mean of 5 degrees medial torsion to 10 degrees lateral torsion, and femoral anteversion decreases from about 40 degrees at birth to about 10 degrees. The result is a lateral rotation of the lower extremity during growth and a gradual decline in the degree of genu valgus until the normal adult stance of minimal genu valgum is reached at maturity (Figure 154-1).

Most functional deformities of the legs and feet are self-correcting in time through this normal developmental progression of the lower extremities. In the past, many of these rotational and positional deformities were treated with stretching, bracing, and even casting. However, studies of these functional deformities comparing treated versus untreated paired-control groups have demonstrated the relative ineffectiveness of treatment for these conditions. Therefore, most physicians choose watchful waiting for these conditions because children naturally grow out of them. A more detailed discussion of these conditions follows.

**Figure 154-1** Positional deformities of the foot and ankle. A, Varus. B, Valgus. C, Equinus. D, Talipes calcaneus.

## ORTHOPEDIC TERMINOLOGY

Orthopedists use a standard terminology to describe positional and structural variations of the lower extremities. In general, the joint that is primarily involved in the condition constitutes the first word; the subsequent word or words relate to the positioning of the extremity relative to the midline of the body. For example, coxa vara is a condition of the hip (coxa) that results in a deviation of the leg toward the midline (varus position). The orthopedic terms in Box 154-1 have special reference to abnormalities of the feet and legs.

## ROTATIONAL DEFORMITIES

### In-toeing and Out-toeing

Rotational deformities of the lower extremities are the most common cause of in-toeing and out-toeing. With in-toeing (pigeon toe), the foot turns inward more than expected during walking or running relative to the line of progression; with out-toeing, the foot turns outward more than expected. Parents, seeing either in-toeing or out-toeing, often become concerned that some intervention is needed. In most cases, these deformities are physiologic, related to normal growth and development, and the appropriate intervention is reassurance.

### BOX 154-1 Glossary of Terms That Refer to Foot and Leg Abnormalities

- *Abduction*: deviation away from the midline of the body
- *Adduction*: deviation toward the midline of the body
- *Cavus*: medial longitudinal arch of the foot elevated
- *Equinus*: foot plantar-flexed, placing the toes below the level of the heel
- *Pes*: the foot
- *Planus*: medial longitudinal arch of the foot flattened
- *Talipes*: congenital deformity describing a foot that is twisted out of shape or position
- *Talipes calcaneus*: a deformity of the foot in which the foot is dorsiflexed
- *Torsion*: excessive or abnormal twisting along the long axis
  - *Internal torsion*: excessive or abnormal inward twisting
  - *External torsion*: excessive or abnormal outward twisting
- *Varus*: medial or inward deviation of the distal segment of an extremity relative to the proximal (previous) segment
- *Valgus*: lateral or outward deviation of the distal segment of an extremity relative to the proximal (previous) segment
- *Version*: physiologic or normal twisting along the long axis
  - *Inversion*: physiologic or normal twist inward
  - *Eversion*: physiologic or normal twist outward
  - *Anteversión*: physiologic or normal twist forward
  - *Retroversion*: physiologic or normal twist backward

In-toeing and out-toeing may be seen at all ages and are caused by a variety of conditions affecting the feet, ankles, legs, knees, and hips. In general, with in-toeing, if the child's patellae are rotated inward (kissing knees) while walking, then the underlying problem will be found above the knee—most commonly femoral anteversion. If the patellae face straight forward, then the underlying problem is likely below the knee—most commonly medial tibial torsion or metatarsus adductus. Less common causes of in-toeing include talipes equinovarus, metatarsus varus, and spasticity of the internal rotator muscles of the hip, as seen in cerebral palsy.

Excessive out-toeing, less common than in-toeing, may be seen with excessive external tibial torsion and femoral retroversion, or with posterior maldirection of the acetabulum, rigid flat feet, and flaccid paralysis of the internal rotator muscles of the hip. Most adults have a mild degree of physiologic out-toeing when standing and walking.

Parents can be reassured that most cases of in-toeing and out-toeing will resolve spontaneously as the lower extremities finish growing. Although in-toeing or out-toeing may reflect a variety of underlying orthopedic diseases, no evidence has been found to suggest that uncorrected in-toeing or out-toeing of normal developmental origin leads to any functional disabilities.

An orthopedic or neurologic evaluation should be made for any child with severe in-toeing or out-toeing, or for an unsteady gait (especially while running) that causes stumbling. A referral may also be advised if a child's condition does not follow the expected physiologic progression with growth.

## Metatarsus Adductus and Deformities of the Forefoot

### Clinical Conditions

Deformities of the forefoot are among the earliest causes of in-toeing noted by parents. The most common and generally benign cause is *metatarsus adductus* (Figure 154-2), a condition in which the only finding is a flexible adduction of the metatarsals at the tarsometatarsal joints. The incidence of metatarsus adductus is generally reported to be approximately 1 in 1,000 live births, but in some studies it is reported to be as high as 1 in 100. There is a slightly higher incidence in the left foot than the right, and 50% to 60% of cases occur bilaterally.

The differential diagnosis of metatarsus adductus includes the uncommon conditions talipes varus, metatarsus varus, and clubfoot. *Talipes varus* (Figure 154-3) is a condition in which the entire foot is inverted and the forefoot is adducted. In *metatarsus varus* (Figure 154-4), the forefoot is inverted and adducted while the hindfoot and heel are in the normal position. Talipes varus and metatarsus varus have been considered lesser degrees of clubfoot and are fixed deformities of the foot that require early treatment.

## Evaluation

### Relevant History

Although its exact cause has not been established, metatarsus adductus is widely considered a packaging defect. There may be a history of oligohydramnios,

uterine fibroids, multiple gestation, or other cause of a crowded intrauterine environment; but such a history is not necessary for making the diagnosis. Metatarsus adductus was previously thought to be associated with developmental hip dysplasia. However, more recent studies do not support the association, and an ultrasound of the hips is no longer required as part of the workup of metatarsus adductus.

### Physical Examination

Metatarsus adductus is graded by both the degree of adduction and the flexibility of the deformity. The severity of adduction is graded by the heel bisector

method. Normally, a line bisecting the heel and sole longitudinally lines up approximately with the second toe. In mild metatarsus adductus, the heel bisector line falls through the third toe, whereas in severe metatarsus adductus, the line falls between the fourth and fifth toes. The heel bisector line can be assessed directly on the child's foot, or the child may be stood up on a photocopy machine to take a photograph of the soles of the feet. A bisector line can then be drawn on the photocopy. An advantage of this method is that it allows for easy tracking of the condition over time.

Next, flexibility of the forefoot should be assessed by holding the heel and abducting the forefoot. With a

**Figure 154-2** Photocopy of the feet of a 9-month-old infant with bilateral metatarsus adductus. (From Greene WB. *Metatarsus adductus and skewfoot*. Instr Course Lect. 1994;43:161–177. Reproduced with permission from American Academy of Orthopaedic Surgeons.)

**Figure 154-3** Talipes varus. The entire foot is twisted inward on its longitudinal axis, and the forefoot is adducted.

**Figure 154-4** Bilateral metatarsus varus. The forefoot is inverted and adducted, and the lateral border of the foot is convex. The hindfoot is in a neutral position.

flexible foot, the second toe can be easily brought in line with or even past the heel bisector line. If the foot is not flexible, then the defect is more consistent with metatarsus varus or talipes varus, and referral should be made to an orthopedist.

### Imaging

Radiographic examination is necessary only when there is limited flexibility of the forefoot to evaluate for talipes varus and metatarsus varus.

### Management

Metatarsus adductus is a functional deformity and requires minimal if any treatment because most cases correct spontaneously during the first year of life. Parents may be instructed to perform simple stretching exercises of the child's foot. The parent holds the heel in place and puts gentle pressure on the medial side of the foot with the other hand, stretching the midfoot and bringing the foot into normal or even slightly overcorrected position. This stretch can be held for several seconds and repeated 5 to 10 times with each diaper change. About 85% to 90% of cases will resolve by 8 to 12 months of age with this simple management. If some improvement is not seen by 6 months of age, referral to a specialist should be made. Most of these refractory cases can be treated successfully with serial casting. Whether through spontaneous resolution or with treatment, nearly all cases of metatarsus adductus resolve without any long-term complications.

Talipes varus and metatarsus varus are fixed deformities of the foot that require early referral and treatment. Treatment consists of serial casting, long-leg splints that abduct the forefoot, or both. Abduction stretching exercises and outflare shoes may be used as an adjunct to cast treatment but should not be relied on as the only therapy. The sooner therapy is initiated, the better the outcome.

### Tibial Torsion

#### Natural History and Presentation

*Tibial torsion* is the rotation of the tibia on its longitudinal axis. Most infants are born with internal tibial torsion resulting from normal growth and the classic fetal position in utero. This turning inward results in mild in-toeing at birth for many infants. The average tibial torsion in infancy is  $-5$  degrees (5 degrees of internal tibial torsion). An increased degree of internal tibial torsion is a common cause of in-toeing in toddlers up to age 3 or 4 years. As the child grows, the tibia externally rotates until a mild degree of external tibial torsion is reached in later childhood. Adults have an average external tibial torsion of  $+15$  to  $+25$  degrees, which accounts for the standard mild out-toeing position seen in adulthood. There is no evidence that patients with unresolved internal tibial torsion experience any increased incidence of knee pain, arthritis, or other conditions later in life. External tibial torsion in early childhood is much less common. It may be idiopathic, or it can be seen with calcaneovalgus foot deformities, as compensation for persistent severe femoral anteversion, or associated with tight iliotibial bands. As the tibia normally undergoes external rotation during growth, external

tibial torsion may actually worsen over time rather than improve.

Pathologic degrees of internal and external tibial torsion are rare and may occur with other significant deformities of the hips or lower extremities, or as a result of improperly applied casts or braces.

### Evaluation

#### Physical Examination

The easiest way to assess tibial rotation is to measure the thigh-foot angle, which is the axis of the foot relative to the axis of the thigh (see Figures 154-5 and 154-6). The infant or child should be placed prone on the abdomen with the knees together and bent to 90 degrees and the ankles in neutral position. The acute angle made between the axis of the femur and the heel bisector is the thigh-foot angle. An internal or negative angle indicates internal rotation; an external or positive angle indicates external rotation. The normal thigh-foot angle at birth ranges widely from  $-35$  degrees to  $+40$  degrees, with a mean of  $-5$  degrees. Thigh-foot angles of  $+10$  degrees and  $+15$  to  $+25$  degrees are the average seen in older children and adults, respectively.

### Imaging

Although studies have shown computed tomography scanning to be an excellent method for measuring the exact degree of tibial torsion, imaging is not required in most cases: physical examination is generally sufficient.

**Figure 154-5** Thigh-foot angle: normal range. (From Alexander JJ. *The Foot: Examination and Diagnosis*. New York, NY: Churchill Livingstone; 1990. Copyright © 1990, Elsevier, with permission.)

## Management

In the past, various forms of bracing, such as Denis Browne splints, were used to treat internal tibial torsion. However, because it is now understood that this condition resolves on its own over time, treatment of primary internal tibial torsion is no longer recommended. Even toddlers who may occasionally trip over their toes as a result of increased internal tibial torsion generally do not need treatment and outgrow the condition by age 6 years. The mainstay of treatment is parental reassurance and education about the natural growth and development of the legs. In very rare cases, when severe residual internal tibial torsion is affecting function, derotational osteotomies may be required. Surgery should be delayed until at least 8 to 10 years of age to ensure that the issue does not self-correct. Surgery may also be required for the rare case of significant external tibial torsion that interferes with function.

## Femoral Anteversion

*Femoral anteversion* is the increased internal rotation or twisting of the femoral neck anteriorly relative to the femoral condyles; *femoral retroversion* is the extreme twisting of the femoral neck posteriorly relative to the femoral condyles. Femoral anteversion is greatest at birth (about 40 degrees) and gradually declines to adult values of 10 to 15 degrees by age 8 years. Femoral anteversion is the most common cause of in-toeing seen in preschool-aged children. Conversely, femoral retroversion is an uncommon condition that results in an out-toeing gait. New

onset of femoral retroversion may occur in older children in the setting of slipped capital femoral epiphysis (SCFE).

## Natural History and Presentation

In utero and postnatal positioning of the legs and hips produces stresses that are thought to bring about these rotational deformities of the femoral neck. The true incidence of excessive anteversion and retroversion is not known. However, femoral anteversion is much more common and occurs twice as frequently in girls as in boys.

## Evaluation

### Physical Examination

Parents of a child with femoral anteversion may express concerns about kissing knees, in-toeing, or a clumsy gait, or they may note that the child will not or cannot sit in the modified lotus position but rather prefers to “W” sit.

The best manner in which to assess for femoral anteversion or retroversion is to place the child in the prone position with the knees flexed to 90 degrees. To measure hip rotation, the lower leg is used as a pointer, and the legs are rotated through the axis of the hip joint (Figures 154-7 and 154-8). Normally the examiner should be able to move the hip through approximately 50 degrees of internal and 40 degrees of external rotation. With excessive femoral anteversion, there will be

**Figure 154-6** Bilateral internal tibial torsion. (From Alexander LJ. *The Foot: Examination and Diagnosis*. New York, NY: Churchill Livingstone; 1990. Copyright © 1990, Elsevier, with permission.)

**Figure 154-7** Starting position for measuring hip rotation with the hip extended while the child is in the prone position. (Reprinted with permission from Joint Motion Method of Measuring and Recording. Rosemont, IL: American Academy of Orthopedic Surgeons; 1965.)

increased internal rotation of the hip of at least 60 to 65 and sometimes as much as 80 to 90 degrees, along with a decrease in external rotation to less than 20 degrees. With excessive femoral retroversion, there will be increased external rotation and decreased internal rotation. Until 1 or 2 years of age, the clinical measurement of hip rotation using this method is limited by the physiologic tightness of the hip joint capsule.

### Imaging

Imaging is only required with severe femoral anteversion. New-onset, severe, or worsening femoral retroversion, however, can be associated with SCFE or other hip disorders, and radiographs should be obtained.

### Management

Most femoral torsion deformities correct themselves by 7 years of age. Children with pronounced femoral anteversion often are noted to sit in a “W” position with the child’s bottom firmly planted between the feet. It is unclear if this sitting position contributes to the development of femoral anteversion, or if children with preexisting femoral anteversion find this position to be more comfortable. Parents who feel the need to intervene can encourage their child to sit in a modified lotus or Indian-style position, while discouraging sitting in the “W” position. They should be informed that these interventions are more anecdotal than evidence based. The use of splints is contraindicated, and corrective shoes are of no value.

**Figure 154-8** Internal rotation. (Reprinted with permission from Joint Motion Method of Measuring and Recording. Rosemont, IL: American Academy of Orthopedic Surgeons; 1965.)

An orthopedist should be consulted if the femoral anteversion does not follow the typical pattern of improvement with growth, if it is associated with difficulty walking or running, or if significant asymmetry of the anteversion exists between the 2 legs. Orthopedic treatment may consist of the use of a bivalve lower trunk and leg cast during sleeping hours or, in rare cases, a derotation osteotomy of the middle or lower femoral shaft. It remains unclear whether untreated excessive femoral anteversion contributes to early degenerative changes and osteoarthritis of the hip. Stronger evidence indicates that persistent excessive femoral retroversion may be associated with degenerative changes, and therefore referral to an orthopedist may be warranted. With femoral retroversion, immediate referral should be made if radiographs reveal SCFE.

## PATHOLOGIC BOWED LEGS AND KNOCK-KNEES

Genu varum (bowed legs) is an angular deformity at the knee with the tibia adducted (varus) in relation to the femur. Genu valgum (knock-knees) is characterized by alignment of the knee with the tibia abducted (valgus) in relation to the femur. These conditions are generally part of the normal growth and development of the lower extremities. Bowed legs, normal at birth, start to correct once children begin to walk and are usually fully resolved by 2 to 3 years of age. Children then become increasingly knock-kneed by age 3 to 4 years, with ultimate resolution over the next several years.

### Differential Diagnosis

Although bowed legs and knock-knees are normal at various stages of growth and development, extremes of either of these conditions, unilateral presentation, or their persistence beyond the normal time of resolution may indicate an underlying pathology. Extreme degrees of physiologic bowing of the legs may occur in the young child, and although even this usually resolves over time without treatment, a basic evaluation should be performed to ensure there is no underlying pathology (Figure 154-9).

Genu varum (bowed legs), when extreme, unilateral, or persistent, may result from a variety of conditions, including rickets, chondroplasia, osteogenesis imperfecta, osteochondritis, neuromuscular disorders, or Blount disease. In addition, trauma, infection, or tumor involving the medial proximal epiphysis of the tibia can result in genu varum.

Genu valgum (knock-knees) is often associated with pronation and is more frequently seen in the overweight child. Causes of severe bilateral genu valgum include rickets, renal osteodystrophy, and skeletal dysplasia. Unilateral genu valgum may be a result of trauma, infection, or tumors involving the lateral proximal epiphysis of the tibia (Figure 154-10).

### Evaluation

#### Pertinent History

When evaluating severe or abnormal genu varum or valgus, a family history of metabolic, renal, or skeletal

**Figure 154-9** Normal progression from bowlegs of infancy through slow evolution to a physiologic valgus angle of about  $12^\circ$  at 3 years of age. (From Gómez JE. *Growth and maturation*. In: Harris SA, Anderson SJ, eds. *Care of the Young Athlete*. 2nd ed. Elk Grove Village, IL: American Academy of Pediatrics; 2010:18)

**Figure 154-10** Clinical photograph of boy referred for evaluation of “knock-knees.” The patient was considered to be within normal limits. (From Greene WB. *Genu varum and genu valgum in children*. Instr Course Lect. 1994;43:151–159. Reproduced with permission from American Academy of Orthopaedic Surgeons.)

diseases should be elicited, along with any history of prior trauma, endocrine, metabolic, or bone abnormalities.

#### Physical Examination

The best way to track the progression of genu varum is to lay the patient down supine, place the ankles

together, and measure the distance between the knees. This distance can be followed over time and can be used as a simple way to demonstrate to a parent that the issue is self-resolving. Similarly, the degree of genu valgum can be tracked by measuring the distance between the medial malleoli when the child is standing with the knees together.

#### Imaging

With extreme or unilateral genu valgum or genu varum, radiographic examination should be obtained to exclude rickets, chondroplasia, osteogenesis imperfecta, osteochondritis, Blount disease, injury to the proximal epiphysis of the tibia, or other pathologic process. Additional targeted laboratory evaluation for underlying metabolic conditions may also be indicated.

#### Management

Simple observation and reassurance are all that are required for physiologic genu varum and genu valgum because these conditions spontaneously correct 99% of the time. When identified, underlying causes of extreme varus or valgum deformities must be effectively treated to improve angulation. Treatment of severe bowing or knocking of the knees caused by underlying disease is determined by the nature of the condition and may include wedge osteotomy, epiphyseal stapling, or nutritional, hormonal therapy. Treatment of mild cases of Blount disease may be attempted with bracing; more severe cases often require surgery.

### CLUBFOOT

#### General

*Clubfoot* or *talipes equinovarus* is a pathologic condition in which the foot and ankle are rigidly inverted, adducted, and plantar-flexed, resulting in a clubbing appearance (Figure 154-11). Clubfoot can easily be

**Figure 154-11** Bilateral congenital clubfoot seen in a newborn. (From Sarwark JF, ed. *Essentials of Musculoskeletal Care*. 4th ed. Rosemont, IL: American Academy of Orthopaedic Surgeons; 2010. Reproduced with permission.)

**Figure 154-12** Clinical photograph of a calcaneovalgus foot in a neonate. (From Sarwark JF, ed. *Essentials of Musculoskeletal Care*. 4th ed. Rosemont, IL: American Academy of Orthopaedic Surgeons; 2010. Reproduced with permission.)

distinguished from benign packaging deformities of the foot that frequently occur in newborns; whereas functional deformities can be placed into normal physiologic position and usually even overcorrected, clubfoot is a rigid deformity that cannot be placed into normal alignment.

The differential diagnosis of clubfoot includes severe metatarsus adductus, talipes varus and metatarsus varus, and *calcaneovalgus* foot, which is characterized by eversion of the heel and forefoot, abduction of the forefoot, and dorsiflexion of the entire foot (Figure 154-12). Calcaneovalgus foot generally resolves in time with stretching exercises.

### Evaluation

#### Relevant History

The cause of congenital clubfoot is unknown. Although it can be associated with conditions such as spina bifida, trisomy 18, or congenital constriction band syndrome, clubfoot occurs as an isolated deformity in otherwise normal newborns in 80% of cases. Inheritance of idiopathic clubfoot seems to be multifactorial, and a specific genetic cause has not yet been

identified. The incidence of clubfoot is approximately 1 in every 1,000 live births. It occurs bilaterally in 50% of cases and affects boys twice as frequently as girls. There is a 3% to 4% risk for recurrence in a family if a prior sibling had clubfoot. When a parent and sibling are affected, future children have upward of a 25% risk. Clubfoot can also develop later in life as a result of neuromuscular conditions such as arthrogryposis and meningomyelocele, and even as a neurologic complication of Wilson disease.

### Physical Examination

Four main components combine to form the defective foot and ankle of a clubfoot: significant and uncorrectable plantar flexion of the ankle; heel and hindfoot adduction; high arch (cavus) at the midfoot; and severe adduction of the forefoot. All combined, the result is a rigidly plantar-flexed, medially rotated, and twisted foot and ankle that cannot be passively manipulated into a normal foot position.

When clubfoot is present, an evaluation for associated neurologic, muscular, or other skeletal anomalies should be performed.

**Figure 154-13** Medial (A) and posterior (B) views of flatfoot. (From Sarwark JF, ed. *Essentials of Musculoskeletal Care*. 4th ed. Rosemont, IL: American Academy of Orthopaedic Surgeons; 2010. Reproduced with permission.)

### Imaging

Although radiographic examination is not generally required for diagnosis, it is useful to delineate the pathologic findings and guide management.

### Management

For pediatricians, treatment of clubfoot entails early and immediate referral to a pediatric orthopedist for either serial casting or surgery. Some institutions report extremely high success rates with serial casting beginning in the first weeks of life and continuing through several months of age. Rates of recurrence vary after correction by manipulation alone. Recurrence after casting is most common within the first 2 to 3 years but may still happen as late as 5 to 7 years of age. Surgical correction (tenotomy, muscle transplantation, and arthrodesis) may be required in severe cases, when conservative management fails, or as a result of recurrence when the child is older. Recurrence is much less likely after surgical correction, although functional outcomes are not necessarily improved compared with more conservative measures. Even with successful treatment, the affected foot is generally smaller and less mobile than a normal foot. Early initiation of therapy increases the success rate of manipulative or conservative management and therefore decreases the need for surgical intervention.

## FLATFOOT

*Pes planus*, or flatfoot, is a very common condition in childhood characterized by the loss or absence of the medial longitudinal arch when weight bearing. It is associated with a pronated gait and stance, eversion of the calcaneus and valgus position of the heel, and prominence of the medial talar head. The condition is best divided into 2 main categories: flexible flatfoot and rigid flatfoot. There is significant disagreement about the clinical importance of flexible flatfoot, if any, and its treatment. Rigid flatfoot is more likely to be clinically significant and to require treatment, although disagreement exists about this condition as well.

### Flexible Flatfoot

Infants are born with flat feet. The normal medial longitudinal arch does not begin forming until about 3 years of age and continues to develop for several years. The prevalence of flexible flatfoot in one study was shown to decrease on average from 54% at

3 years to 24% by 6 years of age. Boys seem twice as likely as girls to have flatfoot at 6 years of age. Overweight and obesity also increase the risk for flexible flatfoot. By adulthood, the prevalence of flatfoot is closer to 10% to 20%.

Prevailing opinion in the past was that flatfoot was a cause of foot, leg, and back pain, and that it interfered with physical activity. This, however, is now not so clear. Some studies suggest that people with flatfoot walk more slowly and have decreased physical performance, whereas other studies, one involving military recruits and one involving teenagers, showed neither disadvantages in performance nor increased injury rates with flatfoot. In short, there remains a lack of general consensus on the clinical significance of this condition.

### Physical Examination

The diagnosis of flexible flatfoot is made clinically; imaging is not required. The patient's foot should be examined while he or she is standing. If flatfoot is present, the examiner will notice a collapse of the medial longitudinal arch and ankle pronation with valgus heel position (Figure 154-13). When viewed from behind, the Achilles tendon is noted to bend medially before arcing back laterally toward the everted calcaneus. To be certain that the condition is flexible, the examiner should have the patient stand on tiptoe: in flexible flatfoot, the medial longitudinal arch of the foot will return; with rigid flatfoot, the sole remains flat.

### Treatment

Treatment of flexible flatfoot remains controversial. If flatfoot is not causing any problems, no treatment is needed beyond parental reassurance. In cases in which the condition seems to be contributing to pain and discomfort or impairing function, flatfoot can be managed conservatively with arch support inserts. If the condition is associated with tight Achilles tendons, stretching may be a beneficial part of treatment.

### Rigid Flatfoot

Unlike flexible flatfoot, rigid flatfoot is more likely to represent a pathologic condition. It can result from tarsal coalition (fusion of 1 or more of the tarsal bones) or vertical talus. Two types of tarsal coalitions have been identified: *calcaneonavicular coalition*,

which involves the calcaneus and the navicular bones; and *talocalcaneal coalition*, in which the calcaneus is coalesced to the talus. Congenital rigid flatfoot occurs in approximately 1% of the population and frequently is bilateral. Rigid flatfoot may also be acquired from trauma, infection, an arthritic process, or neuromuscular disease. In these cases, the condition may be progressive, and any underlying condition should be treated as part of the management of the rigid flatfoot.

### Physical Examination

Examination of a rigid flatfoot reveals a foot with a stiff, flattened arch in both weight-bearing and non-weight-bearing positions. There is no return of a normal arch when standing on tiptoe. This condition is generally associated with a significant degree of ankle pronation. Vertical talus and accessory tarsonavicular can usually be detected in the newborn by the presence of a bony prominence on the medial and plantar aspects of the foot, with limitation of plantar flexion and inversion of the forefoot.

Tarsal coalitions are not usually detected until late childhood or adolescence, when the initially fibrous or cartilaginous bar connecting the hindfoot bones becomes ossified, producing pain with walking and an inability to invert the foot. The foot is held in a pronated position with eversion of the forefoot. The peroneal tendons stand out prominently when attempts are made to invert the foot. Calcaneonavicular coalition tends to develop between 9 and 13 years of age, whereas talocalcaneal coalition develops later, typically at 13 to 16 years of age.

### Imaging

Radiographs may be useful in identifying the exact cause of rigid flatfoot in a patient.

### Treatment

Treatment in most cases of rigid flatfoot is with orthopedic shoes. Surgical correction is required only for accessory tarsonavicular or tarsal coalition if symptoms cannot be relieved through conservative means (only about 10% of cases) and is usually performed in adulthood. Vertical talus usually requires surgical correction early in infancy.

## PES CAVUS

Pes cavus (cavus foot deformity) is an equinus deformity of the forefoot relative to the hindfoot, producing a very high medial longitudinal arch (Figure 154-14). It is referred to as clawfoot when associated with flexion deformities of the toes. The primary pathologic condition is neuromuscular rather than bony, with weakness or paralysis of the intrinsic muscles of the foot and its dorsiflexors leading to the deformity over time. Pes cavus is not seen at birth. Depending on the underlying neuromuscular disease, it usually does not develop until late childhood or adulthood. Pes cavus may be seen in muscular dystrophy, peripheral neuropathies, and diseases of the spinal cord, brainstem, and cerebral cortex. Cerebral palsy, meningomyelocele, poliomyelitis, Charcot-Marie-Tooth disease, and

**Figure 154-14** Clinical photograph demonstrating pes cavus. (From Sarwark JF, ed. *Essentials of Musculoskeletal Care*. 4th ed. Rosemont, IL: American Academy of Orthopaedic Surgeons; 2010. Reproduced with permission.)

Friedreich ataxia are some neurologic conditions that may produce pes cavus as a late manifestation.

### Evaluation

#### Pertinent History

Because pes cavus is not seen at birth but rather develops over time, parents may say they have begun finding it difficult to fit shoes on their child's feet, or they may note that the foot is different in appearance. A review of symptoms may reveal problems with bowel or bladder control consistent with spinal cord pathology. There may be a family history of pes cavus because many of the conditions producing this deformity are inherited.

### Physical Examination

A high-arched foot is the main finding in this condition. Pes cavus takes 1 of 2 forms: cavovarus, in which the calcaneus is inverted with tightness of the heel cord; or calcaneocavus, in which a high arch with normal heel alignment is present, usually from weakness of the calf muscles resulting in increased ankle dorsiflexion and increased plantar flexion of the forefoot.

### Imaging

Radiographic examination may be necessary if surgical management is being considered.

### Management

Early treatment includes exercises designed to strengthen the affected muscles and application of metatarsal pads to the innersoles of the shoes or metatarsal bars to the outer soles. Surgical correction of the fixed deformities may be required if contractures develop.

## TOE DEFORMITIES

### Hallux Valgus

Hallux valgus is a common problem in which the great toe is deviated laterally and the first metatarsal bone is

**Figure 154-15** Common toe anomalies.

deviated medially, causing a prominence to form on the medial aspect of the first metatarsophalangeal (MTP) joint (Figure 154-15). The condition is more common in females than males, and most cases are asymptomatic and do not require treatment other than counseling to wear shoes with adequate toe room and to avoid high heels. Persistent irritation of the overlying bursa from rubbing against a shoe can lead to inflammation and a painful bunion. Frequently, some degree of ankle pronation and flat foot is associated with hallux valgus, in which case a shoe insert may help prevent progression. In severe cases, surgical correction may be necessary.

### Hammertoe

Hammertoe describes a contracture of the proximal interphalangeal joint (PIP) in the second, third, fourth, or fifth toe (Figure 154-15). In an infant, hammertoe is usually hereditary; in an older child, it usually results from ill-fitting shoes. Most cases of hammertoe are mild, cause no pain, and can be left alone. Parents should make sure that the child has roomy shoes that allow the toes to stretch. More severe cases can cause pain, corns (an area of thickened skin overlying an area of pressure on the toes), inflammation, and worsening contractures. In severe cases, surgical correction may be needed.

### Mallet Toe

Mallet toe occurs less frequently than hammertoe. It is a chronic flexion deformity of the distal interphalangeal joint (DIP) (Figure 154-15) that causes pressure on the

tip of the toe resulting in callouses or nail deformities. It usually occurs at the second digit but may affect the third to fifth toes as well. Generally caused by improperly fitting shoes, it may also be idiopathic or congenital, result from trauma, or rarely result from a neuromuscular problem. Most cases of mallet toe are mild, flexible, and need no treatment. When a corn develops over the deformity, shaving and padding will help. In the more severe cases, surgical correction can be performed.

### Claw Toe

Claw toe involves all joints of the toe—fixed hyperextension of the MTP joints and flexion contractures at both the PIP and DIP joints (Figure 154-15). Claw toe is a rare condition but usually occurs in conjunction with a cavus foot, is present in neuromuscular diseases such as Charcot-Marie-Tooth disease, and can occur in inflammatory conditions such as rheumatoid arthritis.

### Curly Toe

In a child with a curly toe, the fourth or fifth toe is usually flexed downward and twisted underneath the adjacent toe (Figure 154-15). Curly toe is quite common in infancy and childhood. If curly toe does not cause symptoms, no treatment is needed. When the condition is severe and causes irritation with shoe wear, surgical transfer of the toe flexor can correct the problem.

### Polydactyly

Polydactyly, the presence of an extra digit (Figure 154-15), may exist as an isolated finding or as part of a more extensive syndrome of congenital anomalies (5% of

cases) such as trisomy 13, trisomy 21, or Ellis-van Creveld syndrome. There is a family history of polydactyly of the toes in 30% of cases, and 50% of cases occur bilaterally. In 80% of cases, the extra digit occurs postaxially. If the extra toe is not causing problems with walking and shoe wear, no treatment is needed. However, the extra toe usually does cause difficulty and is cosmetically unacceptable for most families. In these cases, surgical excision of fully formed digits is generally performed after 9 to 12 months of age, whereas vestigial digits can be removed by suture ligation at birth.

### Syndactyly

Syndactyly, the presence of webbed digits (toes) (Figure 154-15), may exist as an isolated finding or, in rare cases, as part of a more extensive syndrome of congenital anomalies. A family history of the same anomaly is often found. Syndactyly is quite common and rarely causes problems. The interconnection between 2 or more toes can vary from thin skin that partially connects the digits to a bony attachment (synostosis) between parts of the phalanges. Unlike with fingers where surgical separation is needed to obtain finer hand functions, syndactyly in the toes does not necessitate treatment.

### Bunionette (Tailor Bunion)

Whereas a bunion forms on the great toe in association with hallux valgus, the less common bunionette occurs at the fifth MTP joint. When a bunionette develops, the bursa over the lateral aspect of the fifth MTP joint becomes prominent, inflamed, and painful. When padding does not help relieve the discomfort of a bunionette, surgical correction is needed.

## TOE-WALKING

Walking on the toes or the ball of the foot is a variation of normal gait often seen between 10 and 18 months of age as toddlers begin to walk. This variation usually progresses to a toe-heel gait and eventually to the normal heel-toe gait pattern several months later. By parental report, as many as 25% of children continue to exhibit some degree of toe-walking later in development.

### Differential Diagnosis

Bilateral toe-walking beyond 2 years of age may be idiopathic or habitual toe-walking, but the differential diagnosis includes spastic diplegia, tethered cord, and diastematomyelia, muscular dystrophy, and other neuromuscular diseases. Unilateral toe-walking may be caused by spastic hemiplegia, a congenitally short Achilles tendon, a shortened limb, a dislocated hip, or significant tibial bowing on the affected side. Children with idiopathic toe-walking are able to place their feet flat on the ground and even have normal dorsiflexion. However, they prefer to use a toe-walking gait. In rare, extreme cases, this can lead to Achilles contractures and an equinus deformity.

### Evaluation

#### Pertinent History

A full history should be obtained, including birth history, developmental history and milestones, and history

of stooling and bladder control to help find cases with underlying pathology. Children with idiopathic or habitual toe-walking exhibit otherwise normal development, whereas those with a spastic diplegia usually exhibit delays in attaining gross motor skills and walking.

### Physical Examination

A thorough examination is required to rule out underlying conditions. The legs should be examined for evidence of any leg-length discrepancies, joint abnormalities, or limitation in range of motion. A neuromuscular examination should be performed to evaluate for spasticity or abnormal bulk, tone, or sensation that could indicate cerebral palsy, muscular dystrophy, tethered cord, or other neuromuscular disorders. In males, look for hypertrophy of the calf muscles and Gower sign as part of the examination for Duchenne muscular dystrophy. Children with simple idiopathic or habitual toe-walking will have normal neurologic and musculoskeletal examinations.

### Imaging

Radiographic examination is not indicated in most cases of toe-walking. Neuroimaging or other testing may be necessary if the toe-walking is acquired (develops after a period of normal gait) or underlying pathology is suggested by history or examination.

### Management

The only treatment generally required for idiopathic toe-walking is parental reassurance. However, in the child with idiopathic toe-walking beyond 2 to 3 years of age, stretching exercises or a dorsiflexion-assist ankle-foot orthosis may be of benefit. Older children who have developed mild Achilles tendon contractures from toe-walking may require serial casting. If any underlying pathologic cause of toe-walking is found, then treatment for the specific disorder should be initiated. Additional stretching and bracing, the use of ankle-foot orthoses, or casting may also be required for these children.

## SHOES

The foot grows to conform to the shape of the shoe. Improperly fitted or manufactured shoes may be the primary cause of acquired foot deformities and problems. Shoes that do not fit properly can deform an otherwise normal foot, resulting in hammertoes, hallux valgus, bunionettes, corns, and, ultimately, the need for surgery.

### Functions of Shoes

Parents often ask the physician when their child should begin wearing shoes and what kind of shoe should be worn. The shoe has 2 functions, the most important of which is protecting the feet from trauma and extreme temperatures. The second function of the shoe is to provide style. Older children will often sacrifice comfort for style despite parental or medical advice to the contrary.

Support to the foot and ankle is not a function of the shoe except when a pathologic condition is present. Athletes in all sports that place the feet and ankles under severe strain wear low shoes that have soft uppers. Ski boots are worn not to support the foot and ankle

but to make them one with the ski, to ensure response to movements originating in the knee and lower leg. Babies and toddlers usually wear ankle-high shoes, not to provide support to the foot and ankle but to make removing the shoes more difficult for the child.

Style is the only reason for a baby to wear shoes at all until the child begins walking outdoors or is taken out in cold weather. Some babies may gain a certain degree of stability from hard-sole shoes when beginning to stand, but this circumstance has not been shown to enhance learning to walk. In fact, shoes that are rigid prevent foot motion and may diminish the development of the intrinsic musculature of the feet. Properly fitting shoes that have flexible, smooth soles and soft uppers should be recommended. They need not be expensive. Toddlers can go barefoot in a protected environment such as indoors. Sneakers are perfectly adequate for summer wear and for winter indoor wear for older children, but toddlers may stumble in sneakers, which can stick to the floor during the stance and step-off phases of the toe-heel gait that typifies this age group.

### Fitting Shoes

Determining the proper fitting of shoes involves no great science. Given that the foot widens while standing and through the day, these measurements should be made later in the day with the child standing. Both feet should be measured so that the shoes can be fitted to the larger foot. The counter should hug the heel snugly; the length should allow a fingerbreadth ( $\frac{1}{2}$  inch) between the tip of the great toe and the top of the toe box. The foot should fit snugly into the widest part of the shoe; the width should not crowd the ball of the foot and should allow the toes to extend without wrinkling the upper. While still in the store, parents should have the child walk in the shoes to ensure comfort. The shoes should not be expected to stretch to fit. If shoes do not fit, they should not be purchased. Shoes in good condition can be handed down to a younger sibling.

The frequency with which shoes should be changed depends on the rate of growth of the feet, the quality of the shoes, and the degree of their use. Parents are usually able to tell when shoes become too small (or rather, feet become too large) without professional advice. The toes will be felt to press against the toe box, and getting the shoes on or having the child keep them on will be increasingly difficult.

### WHEN TO REFER

- In-toeing and out-toeing
- Severe in-toeing
- Unsteady gait (especially while running) that causes stumbling
- Condition that does not follow the expected physiologic progression with growth
- Metatarsus adductus and metatarsus varus
- Forefoot with limited flexibility
- Condition that appears to be progressing or is not improving with growth
- Tibial torsion
- Extreme rotation (especially when associated with difficulty walking or running)

- Significant asymmetry
- Sudden proximal tibial deviation
- Condition that does not follow the typical pattern of improvement with growth
- Femoral anteversion
- Extreme rotation (especially when associated with difficulty walking or running)
- Significant asymmetry of the femoral anteversion
- Condition that does not follow the typical pattern of improvement with growth
- New-onset femoral retroversion
- Bowed legs and knock-knees
- Severe, asymmetrical, or unilateral genu varum or genu valgus
- Condition that does not follow the expected physiologic progression with growth
- Clubfoot
- Immediate referral to an orthopedist on diagnosis of clubfoot
- Flatfoot
- Presence of a rigid flatfoot
- Symptoms not relieved through conservative management
- Pes cavus
- Referral for evaluation by a neurologist, physiatrist, or orthopedist, individually or in collaboration
- Toe anomalies
- Referral to a podiatrist or orthopedist if the anomaly leads to pain, uncomfortable shoe wear, or ambulation, and if these symptoms do not respond to conservative management
- Toe-walking
- Persists beyond 3 to 4 years of age
- Abnormal neuromuscular examination
- Leg-length discrepancy of  $>1$  cm or other significant physical abnormality on examination

## Chapter 155

# GASTROINTESTINAL HEMORRHAGE

Jeffrey R. Avner, MD

Most causes of gastrointestinal (GI) bleeding in children, unlike in adults, are relatively benign and involve small amounts of blood loss. Although rare, some GI lesions may cause severe bleeding and lead to life-threatening conditions. In addition, GI bleeding may be a symptom of systemic illness or serious underlying chronic disease.

Evaluation of GI bleeding must be systematic. The age of the child, the history, the physical examination, and associated symptoms help focus the workup and allow the physician to identify the source of the bleeding in most cases. Endoscopy and new radiologic techniques are particularly useful for diagnosis and management of many conditions.

Bleeding can occur at any point along the length of the GI tract, from the mouth to the anus. Multiple folds, coils, and villous borders of the GI mucosa provide a large surface area for secretion of enzymes and absorption of water and nutrients. A large vascular supply to the GI tract accounts for an appreciable fraction of the cardiac output, especially after meals. Bleeding may be arterial, venous, or both. Although most bleeds are slow and involve oozing from the mucosal surface, massive bleeding can result from lesions involving high-pressure arteries or a large, engorged venous plexus.

Acute GI bleeding may occur with or without symptoms and can originate in either the upper or the lower GI tract. Chronic bleeding is usually slow and intermittent and may be identified only by occult blood in the stool. The slow nature of these bleeds allows the body ample time to compensate and preserve cardiac output. Signs of chronic bleeding include compensatory tachycardia, iron deficiency anemia, fatigue, pallor, or change in stool color.

**DEFINITION OF TERMS**

It is helpful to divide GI bleeding as originating from either the *upper* GI tract (proximal to the ligament of Treitz) or the *lower* GI tract (distal to the ligament of Treitz). In addition, a variety of terms describe specific characteristics of GI bleeding that may also give clues to the nature, location, and duration of the bleeding.

Hematemesis is bloody vomitus, which usually represents bleeding proximal to the ligament of Treitz. Blood that is altered by gastric acid becomes dark and coffee ground-like in appearance. Bleeding that has little or no contact with gastric acid will be bright red. GI bleeding that occurs proximal to the ileocecal valve and is passed rectally will usually appear as melena: black, tarry, sticky stools that result from the denaturing of hemoglobin by intestinal bacteria and enzymes. Hematochezia (red, bloody stool passed rectally) usually results from distal GI bleeding. Blood is usually mixed with the stool or passed just before or just after defecation. Occasionally, rapid bleeding from an upper GI source combined with the cathartic action of blood can speed transit time and cause hematochezia. Specific types of hematochezia include maroon-colored stools, seen with significant bleeding usually from the distal small bowel, and currant-jelly stools, indicative of intestinal vascular congestion and hyperemia.

**DIFFERENTIAL DIAGNOSIS****Identification of True Bleeding**

Red color appearing in the stool is often assumed to be blood. However, many other substances cause change in stool color. Foods that contain a high concentration of red pigments, such as tomatoes, cranberries, beets, and red fruit juices and gelatin (Jell-O), can cause red stools. Similarly, red-colored medications such as acetaminophen and amoxicillin can be passed in the stools, especially if diarrhea is present. Spinach, licorice, iron, and bismuth (Pepto-Bismol) often lead to dark, black stools, which can be confused with true melena. In infants, *Serratia marcescens* can cause *red diaper syndrome* as a result of the formation of red pigment in soiled diapers stored for longer than 1 day.

Several biochemical tests are available to detect blood in the stool. The most common test, the stool guaiac, uses the peroxidase activity of hemoglobin to catalyze a color change on a test card or paper strip. This highly sensitive test is able to identify even trace amounts of blood. Foods that have peroxidase activity may cause false-positive results if eaten within 3 days of testing: red meat, liver, processed meats, and raw fruits and vegetables, especially melon, turnip, radishes, and horseradish. High vitamin C intake interferes with the peroxidase reaction and can cause false-negative results. Similarly, outdated guaiac cards and prolonged storage may affect the accuracy of the test. Stool guaiac cards are not accurate for testing emesis for the presence of blood because gastric acid can affect the reaction that causes the color change. Therefore, heme testing of emesis should be done with guaiac cards that use a buffered stabilized hydrogen peroxide solution (eg, Gastrocult).

**Nongastrointestinal Source of Bleeding**

Although blood is present in the GI tract, the bleeding may originate from a peripheral source. The most common example of this phenomenon occurs in the newborn period. The infant may swallow maternal blood either during delivery or when breastfeeding if

the mother has bleeding nipples. The Apt-Downey test is helpful in differentiating maternal blood from infant blood. One part of the bloody stool (or gastric aspirate) is mixed with 5 parts of water to lyse the red blood cells. After the mixture is centrifuged, 1 mL of 0.2 normal sodium hydroxide is added to the supernatant hemoglobin solution. After 2 minutes, fetal hemoglobin, which resists the alkaline reduction, remains pink, whereas maternal hemoglobin turns yellow-brown. Melena contains denatured hemoglobin and therefore cannot be used for the Apt-Downey test.

Swallowed blood by a child is usually the result of nosebleeds or bleeding mouth lesions. These nasopharyngeal bleeds can mimic hematemesis or melena. Although rare in children, pulmonary hemorrhage may exhibit acutely as hematemesis or more chronically as melena and anemia. Vaginal bleeding in a newborn with estrogen withdrawal may be mistaken for rectal bleeding. In the menstruating teenager, vaginal blood may affect the accuracy of stool guaiac testing. The possibility of blood being added to the stool by a caregiver suggests Münchausen syndrome by proxy.

### Age at Presentation

#### Newborn

GI bleeding in newborns usually appears as rectal bleeding or blood suctioned from the stomach during routine postnatal care. In many instances, no lesion is readily discernible, and the bleeding resolves spontaneously and permanently. Common causes of GI bleeding in the first 24 hours of life include maternal blood swallowed during delivery and local trauma after nasogastric suctioning. Hemorrhagic disease of the newborn as a result of inherited deficits of coagulation factors or delay in administration of postnatal vitamin K occasionally produces GI bleeding, although it is more common for these disorders to show as diffuse bleeding from venipuncture sites.

Premature infants and newborns who have low Apgar scores are at increased risk for having gastric ulcerations and erosions that can bleed. These lesions are rarely primary, usually resulting from asphyxia associated with a difficult delivery, a cardiac lesion, or sepsis. The diagnosis is made by radiograph or upper GI endoscopy. Newborns who have persistent or severe gastroesophageal reflux can develop esophagitis. Although esophageal bleeding is upper GI bleeding, hematemesis is rare. Rather, the slow bleeding is occult and exhibits more commonly with signs of anemia or guaiac-positive stools. Because a barium swallow has poor sensitivity, pH probe manometry and esophagoscopy are better tests for identifying gastroesophageal reflux. Treatment usually involves histamine-2 ( $H_2$ ) receptor blockers.

Newborns with necrotizing enterocolitis (NEC) usually have a sudden onset of bilious vomiting, abdominal distention, lethargy, and lower GI bleeding. These symptoms usually occur after the first feeding but may be delayed for a few weeks. NEC is most common in premature infants but can occasionally occur in stressed full-term infants. Up to 5% of neonates in intensive care units develop NEC, and the overall mortality rate may be as high as 30%. Complications of NEC

include sepsis and shock. The diagnosis is confirmed by the presence of pneumatosis intestinalis on abdominal radiograph, but this finding is variable. These neonates remain hospitalized for bowel rest and intravenous antibiotics, and they occasionally need surgical intervention.

Intrinsic structural lesions of the GI tract are also a serious cause of lower GI bleeding in the newborn. Intestinal duplication, a tubular structure lined with normal GI mucosa adjacent to the true intestine, can be present anywhere along the GI tract. Duplications can cause lower GI bleeding, either acute or chronic, along with abdominal distention and vomiting. The diagnosis is confirmed by radiograph, computed tomography (CT) scan, or ultrasound. Unrepaired duplications may lead to obstruction, volvulus, or perforation. A volvulus or malrotation of the GI tract should be suspected in any infant who has abdominal pain, bilious vomiting, and melena. However, because these symptoms and signs are often unreliable, the diagnosis should be considered in any newborn who vomits and has guaiac-positive stools. An abdominal radiograph may show loops of small bowel overriding the liver shadow, with paucity of air in the GI tract distal to the volvulus. An upper GI series, barium enema, or both are sometimes needed to confirm the diagnosis. Midgut volvulus may also be diagnosed on CT scan or ultrasound by noting duodenal dilation, fixed midline bowel, and the wrapping of the bowel and the superior mesenteric vein around the superior mesenteric artery (whirlpool sign). Immediate surgical repair is necessary. Vascular malformations can occur anywhere along the GI tract and produce slow or diffuse lower GI bleeding. The bleeding is usually painless, and the color of the blood in the stool will vary depending on the level of the lesion. Vascular malformations may be associated with cutaneous hemangiomas or cardiac defects.

Milk or soy protein allergy can begin as early as the first week of life and exhibit as severe diarrhea, gross blood in the stool, abdominal distention, and vomiting. Older infants may have occult lower GI bleeding and mucus in the stool. The diagnosis is made by clinical response to withdrawal and rechallenge with the offending protein. Infectious enteritis, although rare in the newborn, may appear later in the first month of life. In very young infants, bacterial gastroenteritis, especially that caused by *Salmonella* spp, can cause bloody diarrhea with or without fever; 8% to 13% of infants may have associated bacteremia. Bright-red blood streaks on the surface of the stool suggest an anal fissure. Often associated with hard stools, anal fissures are the most common cause of rectal bleeding. Visual inspection of the anus usually confirms the diagnosis. Medications, such as indomethacin and dexamethasone, can cause mucosal erosion and GI bleeding.

#### Infants and Young Children

Upper GI bleeding in a young child is usually caused by mucosal lesions in the esophagus and the stomach. Infectious esophagitis is usually viral, but fungi can be the cause of disease in immunocompromised children. As infants become more mobile and dexterous, they

are at higher risk for foreign body and toxic ingestions. Coins and small toys, when lodged in the esophagus, can cause drooling, vomiting, and chest pain. Persistent or unrecognized esophageal foreign bodies lead to edema and erosion of the esophagus and may cause hematemesis. Caustic ingestion severe enough to burn the esophageal mucosa can also result in painful swallowing, drooling, oral burns, and hematemesis. Children who have forceful or prolonged vomiting may develop a rent at the gastroesophageal junction known as a Mallory-Weiss tear. The emesis becomes streaked with bright-red blood and may develop into coffee-ground emesis if the tear persists. Although the bleeding is minor and usually resolves spontaneously, an H<sub>2</sub>-blocker may be needed to prevent continued irritation by stomach acid.

Gastroesophageal varices can occur at any age but usually occur in children younger than 8 years. Variceal bleeding can range from slow, persistent oozing to acute massive hematemesis. Physical examination usually reveals signs of portal hypertension, such as enlarged liver or spleen, or both. Most cases result from the cavernous transformation of the extrahepatic portion of the portal vein, which has been associated with umbilical vessel catheterization, omphalitis, or neonatal conditions associated with hypoxia, prolonged jaundice, or sepsis. Intrahepatic causes of cirrhosis, leading to portal hypertension that may first show during childhood, include Wilson disease (>6 years of age),  $\alpha_1$ -antitrypsin deficiency, biliary cirrhosis, and metabolic, infectious, or anatomic forms of chronic liver disease. These chronic liver diseases also may be associated with coagulopathy and thrombocytopenia from the hypersplenism that usually accompanies them. If the cause of the portal hypertension is extrahepatic, then the bleeding may be tolerated remarkably well, in contrast to that in patients who have cirrhotic liver disease, in whom rapid hepatic decompensation may occur. Fortunately, most variceal bleeding stops spontaneously, but the incidence of rebleeding is high. Endoscopy confirms the diagnosis.

Juvenile polyps are the most common cause of lower GI bleeding, reaching a peak incidence in children aged 3 to 7 years. Typically, polyps are located in the colon and are simple, solitary, benign hamartomatous lesions that may irritate the GI tract and cause intermittent, painless, bright-red rectal bleeding. Many of these polyps will autoamputate if left alone and are passed with the stool. Because most polyps are located within 25 cm of the anus, they can often be identified by digital examination, air-contrast barium enema, or sigmoidoscopy and can be removed with snare electrocautery.

Adenomatous polyps may produce rectal bleeding as early as infancy, but they are managed differently from juvenile polyps. Juvenile polyps are benign inflammatory lesions that do not cause later complications. Adenomatous polyps, conversely, are premalignant tumors, which may transform into a malignancy over an average period of 10 years. Familial polyposis and Gardner syndrome are associated with adenomatous polyps. Juvenile polyposis coli (JPC) is suggested by the presence of 5 to 10 juvenile polyps; 10 or more polyps is considered diagnostic. JPC, which occurs in about 10% of patients who have colonic polyps, is

associated with anemia, right-colon polyps, and adenomas.

Meckel diverticulum, a remnant of the omphalomesenteric duct found within 2 feet of the ileocecal valve, is present in up to 2% of the population. The acid secreted by ectopic gastric mucosa, which is usually present in diverticula that bleed, causes peptic ulceration of the ileal mucosa. Meckel diverticulum typically occurs in children younger than 3 years and causes painless, maroon- or red-colored lower GI bleeding. Typically, the bleeding is severe enough to cause the hemoglobin level to fall to about 8 g/dL. Diagnosis is made by technetium-99 scan, which identifies the ectopic gastric mucosa. This test is fairly sensitive but only during active bleeding; thus, a repeat scan is sometimes necessary when the suspicion is high. Treatment requires surgical excision.

Intussusception, the telescoping of an intestinal segment, is seen typically in children 6 to 24 months of age. The occurrence is often idiopathic and usually involves invagination of the distal ileum through the ileocecal valve into the colon. Older children who have intussusception and those who have multiple recurrences may have pathologic lesions that serve as lead points (Meckel diverticulum, polyp, and tumor). The classic presentation begins with intermittent, severe, crampy abdominal pain, with vomiting following shortly thereafter. As the intussusception progresses, lethargy or paradoxical irritability develops. Guaiac-positive stools are seen as the bowel becomes ischemic and may progress to the passage of red bloody mucus, classically referred to as *currant-jelly stools*. The use of screening ultrasound has decreased unnecessary enemas for clinically suspected intussusception. Diagnosis can be confirmed on ultrasound by identification of the layering of intestinal mucosa as a *bull's-eye* or *coiled-spring* lesion. Confirmation of diagnosis, followed by hydrostatic reduction with barium or air enema, is successful in about 70% to 80% of cases, even in those with symptoms for more than 24 hours. Complications include intestinal perforation, peritonitis, and significant bleeding.

Lymphonodular hyperplasia on the mucosa of the terminal ileum or colon may cause painless, blood-streaked stools. Lymphonodular hyperplasia is usually seen in children younger than 6 years and may be associated with food allergy. Diagnosis is made by endoscopic examination and histologic confirmation.

Symptoms associated with infectious enterocolitis range from mild diarrhea to fever, abdominal cramping, and watery or mucoid stools (or both forms) with or without blood. *Salmonella*, *Shigella*, *Yersinia*, and *Campylobacter* spp are the most common bacterial causes of bloody diarrhea. Pseudomembranous colitis, caused by *Clostridium difficile*, also causes fever, diarrhea, abdominal cramping, and bloody stools. In many instances, a history of recent hospitalization and antimicrobial therapy exists, but the onset of symptoms can be delayed for weeks. A variety of parasites, such as *Entamoeba histolytica* and *Trichuris trichiura*, can cause bloody diarrhea.

Systemic disease, in particular vasculitis, may be accompanied by bloody stools. The constellation of arthritis, hematuria, purpura, intestinal cramping, and bloody stools suggests Henoch-Schönlein purpura

(HSP). Children with HSP are at increased risk for intussusception, or they may have severe GI bleeding. Hemolytic uremic syndrome (HUS) often has a prodrome of hemorrhagic colitis caused by Shiga toxin-producing *Escherichia coli* with a serotype O157:H7. The classic triad of HUS includes thrombocytopenia, hemolytic anemia, and renal disease. Milk protein allergy, anal fissures, and congenital anatomic anomalies of the GI tract can also occur in this age group.

### Older Children and Adolescents

Peptic ulcer disease can occur at any age but is more common in older children and adolescents. Symptoms usually begin with epigastric or periumbilical pain accompanied by nausea. GI bleeding is evident in about 50% of children either as hematemesis or as melena. *Helicobacter pylori*, bacteria found in the gastric mucous layer or adherent to the epithelial lining of the stomach, has been causally associated with ulcers. *H. pylori* infection is diagnosed by culture of biopsy specimens from the stomach and duodenum. Serologic tests, which measure specific *H. pylori* immunoglobulin G antibodies, are often unreliable and, therefore, should be reserved for children with endoscopically diagnosed, or radiographically definitive, duodenal or gastric ulcers. Treatment, when indicated, consists of a 7- to 14-day course of any of a variety of antibiotic regimens together with a proton pump inhibitor.

Hemangiomas and other vascular lesions, such as hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome), must be considered in the evaluation for painless rectal bleeding. Its most common form is the larger cavernous hemangioma, either polypoid or diffuse, extending several centimeters through the submucosa of the small or large intestine. The large bowel, specifically the rectum, is the area usually involved in the diffuse type. Cutaneous vascular malformations are often present but may require scrupulous searching to detect. Selective arteriography or digital subtraction angiography may aid in demonstrating the abnormal vessels if they are not visible on direct inspection.

Inflammatory bowel disease may appear in the adolescent age group as episodes of bloody diarrhea, cramping, and tenesmus. The course may be atypical in children, making the diagnosis difficult. Growth failure, weight loss, or anemia with evidence of recurrent bouts of GI bleeding should alert the physician to the diagnosis, which colonoscopy and biopsy usually confirm.

## EVALUATION OF PATIENTS WHO HAVE GASTROINTESTINAL BLEEDING

When evaluating a patient who has GI blood loss, the physician should keep 2 goals in mind. First, the severity of the blood loss must be assessed quickly to expedite appropriate resuscitative measures. Second, the physician must consider the most likely causes so that problems requiring immediate surgery can be separated from those requiring medical evaluation and management. The workup is based on the patient's age and history, the clinical appearance, and the physician's familiarity with the patient. A list of lesions commonly associated with GI bleeding is provided in Box 155-1.

### Relevant History

A detailed history may help the physician determine the location and duration of the bleeding. Particular attention should be paid to the color of the stool and emesis and whether a change has occurred in the preceding days or weeks. Massive amounts of red blood from the mouth or rectum are readily apparent to the parent and the patient. However, the importance of maroon or tarry stools as a sign of GI bleeding may not be appreciated unless the physician asks.

Antecedent symptoms are also a key to identifying many diseases. Vomiting that progresses from bile stained to bloody is seen with intestinal obstruction (volvulus, intussusception, NEC) or with Mallory-Weiss tears. Bloody diarrhea may accompany infectious enteritis, food allergy, and inflammatory bowel disease, or it may precede HUS. Painless lower GI bleeding, if substantial, is seen with Meckel diverticulum or GI vascular anomalies, whereas a smaller amount of painless bleeding suggests polyps or lymphonodular hyperplasia. Fever is common in infectious or inflammatory disorders. Arthritis and rash are seen with HSP. Abdominal pain, fever, and weight loss suggest inflammatory bowel disease. Lower rectal disorders, such as hemorrhoids or anal fissures, produce blood-streaked stools and painful defecation. Young children who have upper GI bleeding should be questioned about foreign body or caustic ingestion. Medication use, especially of aspirin, nonsteroidal anti-inflammatory drugs, steroids, and tetracycline, is a frequent cause of gastritis. A family history of polyps, bleeding disorders, or GI diseases is important. Neonatal history should focus on risk factors for NEC or varices, including umbilical vein catheters, liver disease, and birth asphyxia. Sexual activity or abuse involving anal penetration should alert the physician to anal and rectal trauma.

### Physical Examination

The physical examination should be complete and systematic because clues to the diagnosis may be present in any organ system. The general appearance and vital signs can be helpful in determining the duration of bleeding. Slow, chronic bleeding allows time for physiologic changes such as tachycardia, orthostasis, and decreased pulse pressure. Children may initially appear comfortable but tired and have some degree of pallor. Patients who have acute, rapid bleeds may be in various stages of shock depending on the amount of blood loss. The nose and mouth should be examined for bleeding lesions or burns. The abdominal examination should evaluate for tenderness, bowel sounds, masses, and hepatosplenomegaly. The physician must also look for signs of chronic liver disease, such as the presence of telangiectasias, jaundice, hepatosplenomegaly, and a prominent abdominal venous pattern. With lower GI bleeding, a thorough rectal examination should be performed, with special attention paid to the perianal region, observing for skin tags, abscesses, fissures, bleeding points, or much less commonly, hemorrhoids; the character of the stool; and the presence of occult blood by guaiac testing. Palpation for polyps and pelvic masses must be part of the rectal examination. Eczema may be associated with food allergy. Finally,

**BOX 155-1 Causes of Gastrointestinal Bleeding****NEWBORNS****Upper GI Bleeding**

- Hemorrhagic disease of the newborn
- Gastritis
- Stress ulcer
- Esophagitis

**Lower GI Bleeding**

- Necrotizing enterocolitis
- Duplication
- Volvulus, malrotation
- Vascular malformations

- Anal fissure

GI, gastrointestinal; HSP, Henoch-Schönlein purpura; HUS, hemolytic uremic syndrome; NSAIDs, nonsteroidal anti-inflammatory drugs.

skin lesions such as purpura and petechiae suggest a bleeding disorder, HSP, or HUS.

**Laboratory Testing**

In the setting of GI bleeding, laboratory testing should focus on determining the amount and duration of the bleeding, assessing for coagulopathy, and evaluating for other laboratory abnormalities that may be associated with the underlying disease process. Hemoglobin determination can help assess the level of blood loss, with the caveat that acute bleeding may not lower the hemoglobin level until some intravascular equilibration takes place. An elevated white blood cell count may occur in infectious colitis. Coagulation studies should be obtained, including prothrombin and partial prothrombin times, as well as the platelet count. The prothrombin time may be elevated as a sign of a bleeding disorder or as a result of abnormalities in liver synthetic function. Liver function tests are useful in evaluating suspected liver disease. Serum chemistries can be used to assess renal function, although an elevation in the blood urea nitrogen may result from increased intestinal absorption of

blood with longstanding upper GI bleeding. Any patient with significant bleeding or a low hemoglobin level should have blood sent immediately for blood type and screen in the event of the need for blood transfusion. If bloody diarrhea is present, a stool specimen should be sent for culture and, if appropriate, ova and parasites.

**Imaging**

Most children with GI bleeding require some type of imaging study to locate the source of the bleeding or confirm a suspected diagnosis. The type of study will depend on the age of the child, clinical presentation, and possible diagnosis. Plain radiographic films are generally nonspecific and usually require additional imaging to confirm a diagnosis. Two-view (flat and upright) abdominal radiographs may show signs of intestinal obstruction such as air-fluid levels and dilated bowel loops. Some specific radiographic findings include pneumatosis intestinalis in NEC and intestinal obstruction with absence of gas in the right colon in intussusception. Barium studies can be used to identify intestinal foreign bodies, polyps, lymphonodular hyperplasia, and

inflammatory bowel disease, although, in many cases, endoscopy remains the procedure of choice for diagnosis. Color Doppler ultrasound is becoming increasingly useful as a diagnostic aid in both intussusception and malrotation, but its usefulness depends on the skill of the operator. CT scans are occasionally helpful in defining related anatomic features if the child is hemodynamically stable and either cooperative or sedated. Nuclear medicine imaging studies (Meckel scan, radioactively labeled colloid or red blood cells) or direct angiography can often identify the source of an acute, ongoing bleed.

Wireless capsule endoscopy (WCE) is a relatively new technical innovation used for evaluation of the small intestine, primarily in adult patients but now with increasing frequency in pediatrics. As in adults, a common use of WCE in children is for evaluation of obscure gastrointestinal bleeding. In one recent study, more than 50% of children had the source of obscure bleeding identified with WCE, including ulcerative jejunitis, polyps, angiodysplasia, blue rubber bleb nevus syndrome, and Meckel diverticulum. Some of the limitations of WCE use in pediatrics include the size of the standard capsule that needs to be swallowed and the risk for capsule retention in strictured areas of the small bowel (more common in Crohn disease). However, several studies show that WCE is a practical and safe technique, even in children as young as 2 years.

## MANAGEMENT

For a child who has acute massive GI bleeding, the approach must be the same as that in any other emergency. The physician must approach the patient with an efficient, rational plan in mind that will allow obtaining the pertinent historical information, performing a brief but adequate examination, stabilizing the patient clinically, arriving at a working diagnosis, and instituting appropriate therapy or consultations. Massive upper GI bleeding may lead to vomiting, aspiration, and airway obstruction that requires stabilization of the airway with endotracheal intubation. Administration of oxygen is always indicated. Evaluation of peripheral perfusion, quality of pulses, and capillary refill time assesses the adequacy of circulation. In children, the initial response to hypovolemic shock is tachycardia. In acute bleeds, adequate blood pressure may be maintained with blood loss of up to 30% without replacement.

Tachycardia and capillary refill time are essential criteria in determining the nature of the resuscitation required. Skin turgor and the color of the mucous membranes also should be noted. If signs of shock are present (eg, orthostasis or frank hypotension, tachycardia, poorly perfused extremities, pale mucous membranes, altered mental status), then at least 1 (preferably 2) large-bore intravenous catheters should be placed. Initial laboratory studies include complete blood count, hematocrit, reticulocyte count, coagulation times, electrolytes, blood urea nitrogen, creatinine, liver function tests, and blood typing and cross-matching. If percutaneous venous access is not obtained within a few minutes, then an intraosseous line should be placed, and 20 mL/kg of normal saline should be given rapidly to reexpand the vascular

volume. This fluid bolus may need to be repeated several times. Additional fluid should be given as needed to allow equilibration of these solutions with the extravascular space. With more than 30% to 40% acute blood loss, packed red blood cells should be given as soon as possible.

An appropriately sized nasogastric (NG) tube, preferably of the vented sump type, helps determine the source of bleeding and helps estimate the volume of ongoing blood loss. The tube should be left in place and attached either to low-pressure continuous suction, if vented, or to intermittent suction, if nonvented. The only instance in which NG tube placement may aggravate bleeding is in a patient who has varices. Nonetheless, even in this case, an NG tube may be required to quantitate blood loss adequately.

Controlling the bleeding and determining the specific diagnosis are the next steps in management. If the NG aspirate contains blood, or if the patient has hematemesis, then saline irrigation may be instituted in an attempt to decrease mucosal blood flow and thereby stop profuse bleeding. Although the efficacy of lavage in decreasing and controlling gastric bleeding has not been demonstrated conclusively, it allows easier assessment of the rate of bleeding and helps in removing clotted blood. At the same time, prolonged lavage (>10 minutes) may not allow fibrin clots to form at the bleeding site. Saline at room temperature should be used because irrigation with water can lead to hyponatremia, and iced or cold fluid may cause hypothermia. The saline is instilled through an NG tube and is withdrawn after 3 to 5 minutes. Aspirate returns that do not clear in 10 minutes suggest continued GI bleeding and should prompt additional evaluation.

If the bleeding ceases, then gastroduodenoscopy should be performed to demonstrate the bleeding source and to determine the type of lesion present. Upper GI fiberoptic endoscopy can establish the diagnosis in 75% to 90% of patients. If the bleeding is massive and cannot be controlled with saline lavage, then adequate visualization is not likely to be achieved with the fiberoptic endoscope. If the bleeding is not immediately life-threatening, then arteriography, which can demonstrate bleeding that occurs at a rate of 1.0 mL/min or more, should be considered. More sensitive than arteriography, and less invasive, a sulfur-colloid isotopic study can demonstrate active bleeding at rates as low as 0.1 mL/min. This method demonstrates active bleeding by using a tracer with a very short half-life. In small infants, a large uptake of the isotope by the liver may mask the right upper quadrant. An additional isotopic method of determining the bleeding site consists of injecting the patient with technetium-99 pertechnetate-labeled red blood cells. These labeled cells may remain in the circulation for more than a day and allow repeated imaging to locate the site of intermittent bleeding.

If the lesion is one of mucosal erosion or inflammation, then antacid therapy with or without the concomitant use of an H<sub>2</sub>-blocker may be instituted. For bleeding ulcers, intravenous therapy with a proton pump inhibitor reduces the risk for ulcer rebleeding but does not appear to influence the overall mortality rate. If the bleeding source is variceal, then the cause

of the lesions must be determined, with appropriate treatment of the underlying disease. In particular, liver or portal venous disease should be sought. Clotting factors and platelets should be replaced as indicated.

Variceal bleeding requires special mention because of the many settings in which varices may be seen. The treatment of variceal bleeding in children has evolved over the past 2 decades. Use of balloon tamponade with a Sengstaken-Blakemore tube (an NG tube with additional lumina for a gastric balloon and an esophageal balloon in which the gastric balloon is inflated and traction is applied so that the balloon abuts the gastroesophageal junction and tamponades the variceal bleeding) was effective in controlling most cases of bleeding but had a high incidence of complications. This treatment has been replaced, in most cases, with the use of vasoactive drugs and endoscopy. Previously, the major medical therapy included the use of intravenous vasopressin as a mesenteric vasoconstrictor to reduce portal blood flow and thus decrease variceal pressure. Octreotide, a synthetic peptide similar in properties to somatostatin, decreases splanchnic blood flow, which thereby decreases portal pressure, has less effect on systemic blood flow and is associated with fewer side effects than vasopressin. Pediatric studies (with no control groups) have shown octreotide to be 50% to 63% effective in controlling acute variceal bleeding. Initially, a 1-mcg/kg (maximum of 50-mcg) bolus is infused, preferably through a central or intraosseous line, followed by an infusion of 1 mcg/kg/hr, which may be increased by 1 mcg/kg/hr up to 4 mcg/kg/hr.

Endoscopy is the preferred intervention for variceal bleeding because it can provide both diagnosis and therapy. The most commonly used techniques are endoscopic injection sclerotherapy (EIS), which uses an injection of a sclerosing solution into the varices, and endoscopic variceal band ligation (EVL), in which elastic bands are placed around the varices in the distal esophagus. Endoscopy has been found to be 80% to 100% effective in controlling variceal bleeding. In a randomized controlled trial in 49 children, EVL achieved variceal eradication faster than EIS, with a lower rebleeding rate and fewer complications. Endoclips are a newer technique used in severe GI bleeding; metal devices, applied to the GI mucosa through a flexible endoscope, are used to compress the tissue around a bleeding vessel. In all cases, endoscopy should be performed by an experienced gastroenterologist, with the availability of general anesthesia and endotracheal intubation, if necessary, especially when performed in small children.

Studies in adults and experience in pediatrics, although limited to date, suggest that octreotide should be used as the initial treatment for bleeding varices, followed by endoscopic therapy, either EVL or EIS. If the bleeding continues despite vasoactive and endoscopic therapies, then balloon tamponade can be attempted.

Evaluation for lower GI bleeding differs in several aspects from that for upper GI bleeding. The abdomen, perineum, and rectum are thoroughly examined. Stool must be analyzed for the presence of blood and, when appropriate, for enteric pathogens and for ova and parasites. If diarrhea is present, then the stool

should be examined microscopically for polymorphonuclear leukocytes and mucus, both of which are evidence of bacterial infection. Digital rectal examination should follow in an attempt to discover the presence of anal fissures, rectal polyps, or hemorrhoids. Sigmoidoscopy may be necessary for children who have persistent rectal bleeding to identify polyps or mucosal lesions. The presence of blood originating from above the reach of the sigmoidoscope indicates the need to proceed with other diagnostic studies.

Several different imaging studies are used to evaluate persistent lower GI bleeding. An upright and supine view of the abdomen will reveal signs of obstruction or calcifications. For severe, life-threatening bleeds, angiography can be both diagnostic and therapeutic, depending on the ability to embolize the bleeding vessels. Because angiography has limited sensitivity in detecting slow or past bleeding, it is best performed when bleeding is active.

Children with persistent, active bleeding who are clinically stable should have a radionuclide scan, which identifies accumulation of an isotope at the bleeding site. With a sulfur-colloid isotopic scan, the isotope is extracted rapidly so that background radioactivity is low. Although high-contrast resolution can be found around the bleeding site, it is effective only for identifying rapid bleeding. An isotope-labeled red blood cell infusion has a lower contrast ratio but is better at detecting slower or intermittent bleeds than a sulfur-colloid isotopic scan. A Meckel scan uses technetium-99 pertechnetate, which is secreted by ectopic gastric mucosa, to identify the diverticulum. If the rate of bleeding does not permit the time necessary to perform these studies, then vasopressin or octreotide may be administered parenterally in an attempt to control the bleeding and to stabilize the patient. Air-contrast barium studies or endoscopy can identify sources of more chronic, low-grade bleeding. However, a barium enema or an upper GI series with small bowel follow-through should be the last study performed because they each make the further use of arteriography, isotope scans, and endoscopy impossible for several days thereafter. In cases in which the intestine is compromised vascularly, or when the rate of bleeding is excessive and uncontrollable by more conservative methods, prompt surgical intervention is required. Fortunately, however, conservative measures control most acute episodes of GI bleeding relatively easily; patients who eventually require surgical intervention can usually undergo elective surgery at a later time.

#### WHEN TO REFER

- Upper GI bleed
- Lower GI bleed that is of moderate amount, persistent, or intermittent

#### WHEN TO ADMIT

- Any nontrivial upper GI bleeding, such as that associated with active bleeding, moderate amount of blood, anemia, and abdominal pain
- Significant lower GI bleeding

- Hemodynamic instability
- Anemia (hematocrit)
- Severe abdominal pain
- Associated systemic symptoms (eg, HUS, inflammatory bowel disease)
- Altered mental status or lethargy
- Suggestion of surgical etiology (eg, Meckel diverticulum, intussusception, volvulus)

## Chapter 156

# GENDER EXPRESSION AND IDENTITY ISSUES

Robert J. Bidwell, MD

Throughout history and across many cultures, children and adolescents have, through their gender expression and gender identity, transcended cultural expectations about the meaning of being a girl or a boy. In some times and places, as these children and youths grew into adulthood, they became respected and even revered members of their societies. In others, including the current culture in many parts of the United States, they have been seen as legitimate targets of discrimination and persecution. Issues related to gender expression and gender identity are highly controversial, and the understanding of them is evolving based on increased research and societal changes. In 2013, the American Academy of Pediatrics (AAP) issued a policy statement and accompanying technical report on office-based care of lesbian, gay, bisexual, transgender and questioning (LGBTQ) youth. These give physicians the basic understanding and skills to work in a respectful and relevant manner with children and youths facing issues related to sexual orientation and gender identity. A similar position paper has been issued by the Society for Adolescent Health and Medicine. While sexual orientation (whom one is attracted to) is distinct from gender identity (one’s inner sense of

being female, male, or another gender), in practice these 2 concepts are often interrelated, as the following section will explain.

### DEFINITIONS

Gender is a complex concept that is still not well understood. Researchers and theorists have attempted to study and explain various aspects of gender to improve their understanding of this important part of being human. *Gender role* represents a set of behaviors, attitudes, and interests that a society or culture believes are typically female or male. A child internalizes these cultural gender role expectations by the age of 3 to 5 years. *Gender expression* refers to how an individual signifies gender in terms of dress, speech, interests, and other outward signs. When a child displays behaviors, attitudes, or interests outside the cultural norm for the child’s biologic (genetic or anatomic) sex, it is referred to as *gender nonconforming* or *gender variant* expression. More recent terms include *gender creative* and *gender expansive* expression. For example, boys with gender nonconforming behavior may prefer playing house to playing football, enjoy dressing up in their mothers’ clothes or trying on their makeup, prefer long hair, and be more stereotypically feminine in their mannerisms and speech, as determined by a particular culture. Girls with gender nonconforming behavior may avoid wearing clothes that are culturally more associated with girls, enjoy more physically aggressive play with boys, prefer short hair, and have more stereotypically masculine mannerisms.

In contrast, *gender identity* refers to a person’s deepest inner sense of being female or male (or even something other than female or male) and is often established early in childhood. For most individuals, gender identity is congruent with biologic or birth-assigned sex. For some, it is not. Although their bodies seem to tell them and the world around them that they are female or male, their inner identity is either of the opposite gender or a sense of gender separate from female or male. These individuals are referred to as *transgender*.

Gender identity is distinct from *sexual orientation*, which refers to an individual’s affectional, romantic, or sexual attraction to others of the same sex (homosexual), opposite sex (heterosexual), or both sexes (bisexual).

*Transgender* also is used sometimes as a broader umbrella term encompassing those who do not conform to cultural norms of being female or male. This group includes individuals whose gender identity is incongruent with their biologic gender and who may seek to change their bodies to make them more consistent with their inner sense of gender. These individuals are sometimes referred to as *transsexual*, but more commonly are referred to as transgender in the narrower sense of the term as described above. Transgender in its broader sense recently has been referred to as the *trans\* spectrum*. In addition to those who experience an incongruence between their bodies and their inner gender identity, the trans\* spectrum also includes those who cross culturally defined gender boundaries, including crossdressers (transvestites),

drag kings and queens, and persons who perceive themselves to be of both genders (bigender), all genders (pangender) or no gender (agender). It also includes those who may refer to themselves as *genderfluid* or *genderqueer*, or who are routinely gender nonconforming in terms of their attitudes, interests, and behaviors. The term *transgender* is not used in referring to prepubertal children with gender dysphoria or gender nonconforming behavior.

In this chapter, *transgender* is used in its narrower sense, referring to gender identity. Transgender individuals often refer to themselves as *trans*, *trans\**, *TG*, or *T*. Many transgender people, but not all, experience significant *gender dysphoria*, a persistent discomfort with the gender assigned to them at birth and the societal gender role expectations that accompany it. These dysphoric feelings often begin in early childhood and increase with the appearance of unwanted physical changes at puberty. Many transgender individuals gradually let go of the need to conform to societal expectations attached to their birth-assigned gender and increasingly present themselves to the world in a manner consistent with their gender identity. This process is known as *transition*. The transition process may be facilitated medically by pubertal suppression, cross-gender hormonal treatment, and/or gender-affirmation surgery (also referred to as sex-reassignment surgery or SRS). However, it not only is a physical process but also takes place on psychological, social, and spiritual levels. The terms *male-to-female* (MTF) and *female-to-male* (FTM) transgender are used to describe the direction of transition from biologic gender to actual gender identity. An FTM transgender person is often referred to as a *trans-man* and an MTF person as a *trans-woman*.

Most gender nonconforming children and youths do not experience gender dysphoria nor do they have gender identities that differ from their birth-assigned sex. The prevalence of gender nonconformity in children and youth is uncertain, although studies have shown that gender nonconforming behavior is common. Persistent gender nonconforming behavior or expressed wishes to be another gender are less common. In a 2011 population-based survey of middle school students in San Francisco, when given a choice of identifying themselves as male, female, or transgender, 1.3 percent chose the latter response. The World Professional Association for Transgender Health (WPATH) estimates that the prevalence of MTF transgender identity is 1 in 11,900 to 1 in 45,000 individuals and of FTM transgender identity is 1 in 30,400 to 1 in 200,000. Some believe that these estimates are low because they are based on individuals seeking hormonal and surgical transition services: some transgender individuals do not have access to or do not want sex-reassignment services and so are not represented in the data.

One of the most controversial issues related to gender expression and gender identity during childhood and adolescence is whether gender nonconformity and transgenderism are causes for concern. Do they represent a pathologic abnormality, or are they simply part of the continuum of normal human

expression and identity? Similar debates occurred around homosexuality until it was officially removed from the American Psychiatric Association's list of mental disorders in 1973. Although controversial, until 2013 transgenderism (in the narrower sense) and transsexualism were represented in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* under the diagnostic category of *gender identity disorder (GID)*. Based on the work of the DSM-5 Workgroup on Sexual and Gender Identity Disorders, the APA fifth edition (*DSM-5*) introduced several important changes in terminology and diagnostic criteria related to gender identity, with separate criteria for children and for adolescents and adults. The diagnostic category of GID was replaced by the less stigmatizing designation *gender dysphoria*. The controversy surrounding these diagnoses is well documented. The diagnostic criteria for both childhood and adolescent/adult gender dysphoria require a marked difference between an individual's experienced or expressed gender and the gender assigned at birth. For a diagnosis of gender dysphoria to be made, this gender incongruence must have persisted for at least 6 months and resulted in significant distress or impairment in social, school, occupational, or other important areas of functioning.

At a basic level, the move from GID to gender dysphoria emphasizes that no longer is cross-gender *identity* considered disordered. Instead, it is the distress related to having a cross-gender identity, which is often caused in significant measure by growing up and living in a nonaccepting, often aggressively hostile societal environment. Much of the controversy arising from the creation of both GID and gender dysphoria as DSM diagnostic categories is the observation that any gender-nonconforming child or adolescent raised in a society that enforces a binary view of gender will predictably experience some degree of discomfort or distress related to gender expression and identity. Given the overt discrimination and violence that have occurred against transgender individuals in the United States, distress or impairment in social and other areas of functioning is not surprising. Evidence suggests that transgender individuals growing up in more accepting societies experience less discomfort and distress related to their gender identity and gender expression.

Several developmental trajectories have been described for children with GID, which presumably are relevant for those now diagnosed with gender dysphoria. The diagnostic rubric of gender dysphoria is too recent to be reflected in a substantial body of literature. The studies on which these proposed trajectories are based are small and inconclusive. Taken as a whole, however, they suggest that many children diagnosed with GID (and more recently gender dysphoria) eventually self-identify as gay or bisexual as adolescents or adults and no longer experience gender dysphoria. A smaller percentage later self-identify as heterosexual and also experience no gender dysphoria. A small but significant percentage continue to experience discomfort with their biologic sex and self-identify as transgender.

## ETIOLOGY

Considerable controversy exists around possible causes for the development of persistent gender nonconforming expression, cross-gender identity, and gender dysphoria, which are related yet distinct phenomena. Theories proposed have suggested psychosocial, biologic, and genetic factors, or varying combinations thereof. However, research data are very limited, often narrowly focused, and sometimes contradictory. Therefore, to date there are no scientifically supported explanations for how gender nonconforming expression, gender identity, or gender dysphoria arise. Nevertheless, among all theories offered, those suggesting a biologic or genetic basis for cross-gender expression and identity are gathering the most robust scientific interest and support. Recent reviews have documented what little is known and how much still needs to be learned about the origins of gender identity and expression and the developmental trajectories experienced by gender nonconforming and gender dysphoric children and youths.

Psychosocial theories seeking to explain gender nonconforming expression and gender dysphoria often focus on familial, and particularly parental, psychopathology, and aberrant parenting practices that may interact with biologic factors and predispose a child to gender dysphoria. Zucker, for example, posits that some children may experience subtle biologically or genetically related prenatal events affecting areas of the brain that lead to gender nonconforming behavior or personality traits. This may in turn interact with parenting styles or psychopathology that encourages persistent gender nonconforming behaviors and possibly the development of gender dysphoria. Much of the controversy around such theories, in addition to a lack of robust scientific evidence to support them, is that many feel they are similar to earlier theories related to the origins of homosexuality, later discredited, that saw aberrant parenting and familial psychopathology as probable etiologies. This is especially relevant because research demonstrates that most gender dysphoric children and many gender nonconforming children later to come to recognize a lesbian, gay, or bisexual orientation in adolescence or adulthood. Psychosocial theories are no longer generally accepted as primary causal explanations for variances in gender expression and identity, while their role in informing the treatment approach to gender dysphoria remains highly controversial. Some have suggested that a more likely route to gender dysphoria for some children is growing up in a home and community that pathologizes their gender expression and identity, although this theory, like all others, lacks robust research support at this time.

Most recent scientific attention has focused on possible biologic, genetic, and neurologic explanations for gender nonconforming expression, cross-gender identity, and gender dysphoria. No clear unequivocal biologic markers for these have been identified, but early limited findings are intriguing and invite further research. One area of inquiry has examined the possible influence of prenatal maternal androgens on those areas of the developing fetal brain associated with sexual dimorphism. There is some evidence that prenatal

androgen exposure may predispose an individual to male gender identity, but not always; among 46, XY intersex children exposed to increased androgens prenatally but raised as girls, only 40% to 50% developed male gender identity. Also, MTF transgender individuals with presumed normal male prenatal levels of androgen exposure override this influence and develop a female gender identity. Recent studies examining 46, XX individuals exposed to higher levels of prenatal androgens demonstrated marked masculine gender expression but no evidence of male gender identity or gender dysphoria. In this area of inquiry, data suggest that for some gender nonconforming and transgender individuals, prenatal exposure to androgens may be influential, but it seems not to be applicable to the broader transgender community.

Recent research provides incomplete but increasing evidence for a genetic component to gender nonconformity and cross-gender identity. Hare and colleagues have identified an association between longer androgen receptor (AR) gene polymorphism and MTF transsexualism, perhaps caused by inhibition of the ability of testosterone to masculinize the fetal brain. A similar gene anomaly has been associated with FTM transsexualism. Familial and twin studies have documented increased occurrence of gender nonconforming expression and cross-gender identity within families and between twins, providing further evidence of a possible genetic component to the development of cross-gender identity and expression.

Another focus of biomedical inquiry has been comparison studies of transgender and nontransgender individuals looking at sex-related anatomic dimorphism in terms of brain structure and functioning. Differences have been reported, but most of these studies have not been replicated and therefore the significance of their findings is uncertain. However, documenting brain differences between transgender and nontransgender individuals would suggest a possible neurologic component to the development of cross-gender identity, at least for some individuals.

Given the complexity of gender as a concept, and the diverse ways in which it is experienced and expressed within a population, continuing research may find that the origins of gender expression and identity are multifactorial, with genetics, biology, and environment each playing a role in varying combinations and degrees of influence. Since gender nonconformity and cross-gender identity do not appear in the *DSM-5*, and therefore may be considered part of the normal spectrum of human experience, perhaps the most valuable research will be that which examines the factors contributing to gender dysphoria among children and adolescents. With this increased understanding, physicians and other providers will be better able to prevent the onset of dysphoria or to ameliorate its effects in the child where it already exists.

## ADVERSE EFFECTS

Due in large part to the experience of societal stigma and ostracism, gender nonconforming and transgender youths may be at high risk on many fronts, as outlined in the paragraphs that follow. Nevertheless, there are reasons for immense optimism because

these young people are coming of age on the cusp of enormous and positive societal change. This change is marked by an increased understanding and celebration of the diversity of gender expression and identity and an awareness of how this diversity can enrich families, schools, workplaces, and the broader community. In many parts of the United States, primary care physicians (PCPs) have begun to recognize the amazing creativity and resilience of these youths as they navigate changing societal currents. They have met parents who love their children unconditionally and who confidently and passionately work to make the world a safer, more accepting place for them. They have joined with educators, social workers, mental health professionals, and others to create empowering transgender youth programs, including youth leadership workshops, mentorship programs, music/poetry/art events, speakers' panels, and many others. Such programs help develop important life skills but just as importantly validate the rightful place of gender nonconforming and transgender youth among other happy, healthy, and hopeful young people. These exciting changes have not yet arrived in many parts of the United States, but they are on the horizon. The risks described below are still very real for many children and youths. But it is important to recognize that they are an aberration, a result of living in the presence of stigma and ostracism. They are not part of the natural history of being gender nonconforming or transgender.

In those communities where the societal change described above has not yet arrived, transgender youths often experience a profound isolation that intensifies their feelings of confusion and distress. They and most people in their lives, including parents, teachers, counselors, clergy, and physicians, often know little about gender identity or what it means to be transgender. In many instances, gender identity is confused with sexual orientation, a much different concept. Many PCPs and counselors were trained at a time when gender nonconforming behaviors and transgender identity were seen as aberrant or pathologic, and some continue to conduct their practices accordingly. Many transgender youths have few adult role models or mentors for support or validation, and many know no other transgender youth. When transgender youths have little access to accurate information, supportive counselors, or physicians, and when they have no opportunity for healthy interactions with transgender peers and adults, the negative messages that surround them in their daily lives go unchallenged. Although this continues to be true in many communities across the United States, over the past decade there have been major advances in increasing the understanding of families, health and social service providers, educators, and others about the importance of recognizing, validating, and empowering gender nonconforming and transgender youths. PCPs have often been at the forefront of the movement to increase public awareness, developing creative programs for youths and their families, and providing needed advocacy on their behalf. With the growing love and support of families and communities, many gender nonconforming and transgender

youths no longer struggle under the burden of stigma and ostracism.

For those many children and youths who grow up in families and communities still untouched by this societal change, the most harmful reality they face is society's disapproval of who they are and how they present themselves to the world. Social stigma, and the violence and discrimination it engenders, permeate their daily lives. It makes completing the expected developmental tasks of childhood and adolescence related to identity and self-esteem enormously difficult. Many of these children and youths are viewed by their families with shame and disgust. They are often forced to change their behaviors and renounce their declared inner sense of gender. Many of them are taken to therapists for the express purpose of changing their gender expression or identity. Many transgender adolescents and adults recall being ridiculed, ostracized, or beaten for being true to who they were, including within their own families. Many gender nonconforming and transgender youths drop out of school and run away or are thrown out of their homes; some seek survival on the streets; many contemplate or attempt suicide. As a result, many end up in the child welfare or juvenile justice systems. The harassment and abuse against gender nonconforming and transgender young people often continue in these settings, perpetrated both by other youths and by staff members. Fortunately, state judiciaries across the country as well as organizations such as the Child Welfare League of America and the Equity Project, with the active involvement of pediatricians and other advocates, have developed training, model policies, and other tools to meet the needs of transgender youths in out-of-home care and address the societal antecedents that bring them into these systems.

Schools often are especially dangerous places for gender nonconforming children and transgender youths. Many of them experience daily verbal, physical, and sexual harassment on the playground and in the classroom. In many instances, this harassment is not addressed by teachers, counselors, or other school staff, or it is dealt with by blaming the victim. Sometimes, disapproving teachers and other school staff members engage in harassing behaviors themselves. Many schools have no specific policies prohibiting harassment or bullying based on gender identity or expression, even though these, along with sexual orientation, are among the most common targets of harassment on school campuses. An increasing number of school systems, however, are adopting rigorous anti-bullying programs and antiharassment policies that specifically include harassment based on gender identity and expression. Many have included transgender issues in regular teacher trainings and have worked with national organizations such as the Gay, Lesbian and Straight Education Network (GLSEN) to ensure that school campuses are safe places for transgender students. Many school systems have encouraged the establishment of gay-straight alliances in schools to support LGBT students and their friends. Many schools also routinely invite PCPs to join in the development of individualized education programs (IEPs) and participate in other discussions related to

addressing the needs of individual gender nonconforming and transgender students.

Societal stigma also may be reflected in the daily discrimination experienced by some children and youths. Children may be admonished for playing with toys or displaying interests that are considered inappropriate for their presumed gender. They are told by what names they will be called and by what pronouns they will be referred to, in spite of their protests that these names and pronouns do not reflect who they really are. Their genitalia rather than their inner identity as female or male are referenced in assigning them to bathrooms, lockers, physical education classes, athletic teams, graduation ceremonies, and other school activities in which gender is still considered relevant. School dress codes often limit transgender students' ability to wear clothes that are consistent with their gender identity. Many PCPs have begun to work with individual schools on behalf of their gender nonconforming and transgender patients, advocating policies and accommodations that ensure safety, respect, and validation for their patients in the school setting.

As transgender youths grow older, they begin to experience broader societal forms of discrimination. Their driver's licenses and other forms of identification, as well as their school, employment, and health records, usually reflect their biologic sex rather than their gender identity. Because fear, embarrassment, and potential humiliation accompany the presentation of these documents to others, many transgender adolescents may avoid applying for school or a job or accessing health care. Transgender individuals have been denied access to educational opportunities, community programs, social services, and health care simply because of their gender identity. Fortunately, each year more states and municipalities enact laws and ordinances that prohibit discrimination based on gender identity and expression in the areas of housing, employment, public accommodations, and health care, providing transgender individuals, including adolescents, legal recourse when faced with discrimination. In addition, LGBT communities have made great strides in recognizing that LGBT social and health services should be as welcoming and accessible to transgender individuals as they are to members of the lesbian, gay and bisexual communities.

The risks described above are not inherent in being a gender nonconforming child or transgender youth. They are the common experience of any young person who is stigmatized, fearful, and alone. The genuine distress experienced by some children diagnosed with GID (and presumably gender dysphoria) and some transgender youths over the perceived dissonance between their biologic sex and gender identity should not be dismissed or minimized. Nevertheless, evidence from other cultures and the experience of many counselors and physicians suggest that when provided love, support, and validation, these young people thrive and can expect to grow into happy, healthy, and productive adults. Perhaps the most important role that PCPs can play in the lives of gender nonconforming children and transgender youths is to go beyond the confines of their offices and engage with schools, social service agencies, faith communities, and others

to ensure that these young people grow up in safe and nurturing environments.

## EVALUATION

The AAP, the American Academy of Child and Adolescent Psychiatry, and the Society for Adolescent Health and Medicine have each issued official guidelines related to providing supportive care to children and adolescents facing issues of gender identity and gender expression. In addition, several resources are available to PCPs on providing culturally sensitive and relevant care to gender nonconforming children and transgender adolescents and adults.

PCPs should not presume the sexual orientation or gender identity of any patient. Children with gender nonconforming behaviors, many of whom will later identify as LGB, have often learned or have been pressured to change their behaviors, particularly in public settings such as schools and health clinics. Many transgender youths will also hide their true gender identity. Even when asked in a sensitive and nonjudgmental manner about their inner feelings of being female, male, or another gender, they often will deny these feelings because they are fearful of PCP disapproval, uncertain about confidentiality, or still confused about the meaning of their emerging feelings. Perhaps one of the greatest barriers to appropriate health care for gender nonconforming and gender dysphoric children and transgender youth is physicians' assumption that they have no patients in their practices who are dealing with issues of gender identity and expression. Another mistaken assumption is that significant gender nonconforming behavior in childhood accurately predicts sexual orientation. Although some children with persistent gender nonconforming behaviors will later identify as LGB, many will not. Few PCPs may consider that some may also later identify as transgender. Many transgender youths are thought by their PCPs, and sometimes by themselves, to be LGB. However, the distinction between sexual orientation and gender identity is important for the provision of care because the different issues related to each require different responses from a PCP. In addition, transgender identity does not predict sexual orientation. Transgender youths may be gay, lesbian, heterosexual, or bisexual. For example, an MTF-transgender adolescent who is attracted to boys may be considered a heterosexual trans-woman, if she so considers herself. Some, however, may describe themselves as "gay," either because it feels like the appropriate term to them or because it is easier for others to understand.

The goal of PCPs is not to identify every child with gender nonconforming behaviors or transgender identity; instead, it is to create a safe and accepting clinical setting where children, adolescents, and their families know they can discuss any topic of concern, including gender identity and expression, without discomfort or disapproval on the part of the physician. Some patients and parents do not know that PCPs may have expertise in discussing issues of sexual and gender development. Specific messages can be provided through clinic posters and brochures informing patients that these issues are appropriate topics of discussion. The most important signal that

these topics are a natural part of pediatric practice is in the PCP's own history taking and anticipatory guidance, in which issues of child and adolescent sexuality and gender should be routinely discussed.

After patients have identified themselves as transgender, the PCP should create an accepting and supportive clinical environment by using pronouns consistent with their patients' gender identity and asking by what name they would like to be called by clinic staff. Although medical records must retain the patient's legal name, the notice "Also Known As [preferred name]" can be added to the front of the chart, and all clinic staff members should use this name in personal encounters with the patient. Patients should use either a unisex restroom or a restroom consistent with their gender identity while in the clinic. As with all adolescents, transgender patients should be seen alone for at least part of each visit and their confidentiality should be respected. An adolescent patient's gender identity should not be revealed to parents without the patient's permission. Patients should also be asked how they would like their gender identity recorded in the chart, if at all, because medical records containing confidential information are sometimes accessible to parents.

PCPs should reflect on their own feelings about gender nonconforming behaviors and gender identity issues. As products of their own society, many physicians may initially approach these issues with discomfort or disapproval. However, such an approach to gender nonconforming children or transgender youths will diminish the PCP's ability to care for these patients. Most transgender patients have had profoundly negative experiences with the health care system. In the past, these patients have been labeled as disordered and were often treated accordingly. Transgender patients report how staff in clinical settings often display fear or open disapproval of them or joke about them, even within hearing of the patient. At times, these patients have been refused medical care. PCPs who receive little training about transgender health issues often do not understand the transgender adolescent's unique life experiences and needs. Most PCPs are unfamiliar with community resources that might help their transgender patients. Most health insurance companies refuse to pay for transition treatments, including hormone therapy, surgery, and the laboratory studies needed to monitor treatment. Fortunately, this refusal of payment for necessary, even lifesaving, care is slowly beginning to change.

PCPs are in a position of power relative to their transgender patients. As gatekeepers, PCPs decide who does or does not receive transition treatments. Many, often through disapproval or lack of knowledge, have barred transgender patients from passing through that gate, preventing them from receiving necessary transition treatment and care. PCPs must understand the history of tension between the transgender and medical communities. PCPs can improve this strained relationship by listening carefully and respectfully to their patients' life stories and expressions of need and by providing care that addresses these needs in a compassionate, comprehensive, and timely manner.

## History

Gender and sexuality are important parts of a child's life. At each well-child visit, beginning in early childhood, the PCP should ask parents how they think their child is developing compared with other children. Parents and child should be asked how the child is getting along with siblings and peers. Does their child seem happy? Is the child teased or harassed by other children, and over what issues? All parents should be asked if they have any concerns over their child's sexual development or gender expression. Many parents who have such concerns are hesitant to bring them up on their own but are often relieved when the PCP does so. If a child with gender nonconforming behavior is happy and safe from teasing and parents have no concerns about these behaviors, no reason exists for the PCP to question further. However, as a child grows older and has more social contacts beyond the family, issues will likely arise related to being gender nonconforming or transgender in a society that is often nonaccepting. PCPs should remain attuned to this likelihood and reopen the door to discussion of these issues in future visits.

If parents express concerns about their child's gender expression or gender identity, then the PCP should ask what they have noticed or heard from the child and what their concerns or fears might be. Parents' concerns are often related to their own embarrassment because of their child's behavior; they may also fear for their child's safety in a nonaccepting world. Many of them fear that their child's behavior or verbal expressions of wanting to be the opposite gender signal an eventual lesbian or gay sexual orientation or transgender identity. PCPs may gently question gender nonconforming children if they feel safe from teasing at home and school and about their feelings of being more like a girl, a boy, or another gender inside. Care must be taken to avoid conveying the message that anything is wrong with the child because of the child's gender nonconformity. In addition to the well-child visit, any visit suggesting an unhappy child or a child in distress should lead the PCP to consider discussing issues of gender nonconforming expression and gender identity with the parents and child.

Transgender adolescents may come to the PCP's office either because of parental concerns or through school or child welfare agency referral. Transgender youths may also seek care themselves, often to discuss issues of safety and acceptance at home or school or concerns about sexually transmitted infections (STIs), or to request hormone treatment. However, many transgender patients see their PCPs not through referrals or acute care visits but rather in the context of routine well-teen evaluations. Many transgender patients hide any evidence of their inner gender identity; others are presumed, perhaps even by themselves, to be lesbian or gay. PCPs should initiate discussion of sexuality and gender with all adolescents at each well-teen visit. Although many PCPs routinely discuss sexual activity and safer sex practices, fewer discuss sexual orientation, and almost none of them address gender identity. However, as noted earlier, most transgender adolescents face significant confusion and distress related to their gender identity and major risks

from growing up in an often nonaccepting world. PCPs must be willing to open the door to discussion of gender in order to reduce the turmoil and dangers that these youths face.

The PCP can begin to approach the issue of gender identity in the broader context of obtaining a HEADSSS (home, education, activities, drugs, sexuality, suicide, and safety) interview. This approach will provide a sense of how things are going in various aspects of an adolescent's life, recognizing that many transgender youths face serious issues in each of these areas. Throughout this conversation, it is essential that the PCP use non-heterosexist, gender-neutral language, reflecting that no assumptions are being made about a youth's sexual orientation or gender identity, or that of family members or friends. To address gender identity within a broader sexual history, the PCP might say, "Sexuality and sexual feelings can be confusing sometimes. During puberty, bodies change in lots of different ways. Sexual feelings are changing as well. Some of my patients are not sure if they are attracted to guys or girls or maybe both; and some of my patients even wonder if they're more like a girl or a boy inside. All of this is completely normal but can be really confusing. So I'm wondering what it's been like for you." After asking about attractions (sexual orientation), the PCP can simply ask, "And how about inside? Do you feel more like a girl or a boy or maybe something else?" For the patient who is not dealing with gender identity issues, these questions may seem odd. This can be addressed by a simple statement such as, "These are questions I ask all my patients, and for some, they're really important." For transgender youths, the questions may be life saving. Even if they decide not to acknowledge their gender identity concerns at the current visit, they have learned that someone is available with whom they can talk when the time is right. If youths do acknowledge cross-gender feelings, the PCP can ask whether they have defined themselves in terms of gender. Some may refer to themselves as transgender while others may self-define as pansexual, pangender, bigender, genderfluid, genderqueer, or another designation. Some may refer to themselves as gay or lesbian. It is appropriate to ask each teen what their particular self-designation means to them. This demonstrates respect on the part of the PCP and can foster a sense of empowerment in the youth.

If adolescents acknowledge a transgender, pangender, or other-gendered identity, the PCP should thank them for their trust in sharing this important and personal part of who they are. As a demonstration of understanding and respect, the PCP should then ask about preferred name and pronouns and use these through the remainder of the interview and subsequent visits. Patients should be reassured that the discussion of gender identity will remain confidential unless they give permission to share it with others or unless a risk of danger to someone exists. It is essential to ask, at an appropriate time in the interview, "Do you have any periods of feeling very sad? How long do they last? Have you ever had feelings of wanting to hurt yourself or kill yourself? Have you ever actually tried to do this?" If the PCP is not comfortable with the depth of interviewing suggested in the following

paragraphs, she or he has a responsibility to refer the adolescent to someone else who can have this conversation.

The subsequent history may then focus on the adolescent's path to recognizing their transgender identity. When were they first aware of feeling more like a girl, a boy, or another gender? What was this experience like? How comfortable are they with their transgender identity now? What do they know about gender identity and what it means to be transgender? What are their hopes and dreams for the future? Do they see their futures as enhanced or limited by being transgender? The history may focus on the adolescent in the context of the world around them. Have they told others (family, peers, teachers, or counselors) about their inner feelings of gender? Have these people responded in a supportive or negative way? Have they been bullied, harassed, scolded, ridiculed, or teased because of their gender identity? With whom do they spend time, and what kinds of things do they do together? Have they met other transgender adolescents or adults? Have they been in relationships, and have these relationships been healthy ones? Have they been sexually active, and do they use safer-sex practices? How have they met their sexual and romantic partners? Have they ever been pregnant, impregnated anyone, or had an STI? How many different sexual partners have they had, and what have been their genders? Have they ever been touched sexually or forced to have sex without their permission?

Understanding that transgender youths often are subjected to harassment and rejection at home and school, the PCP should ask about their treatment in these settings and whether they have ever run away from home or dropped out of school. Have they needed to sell their bodies, deal drugs, or engage in other illegal activities to survive on the streets? Have they been involved with the child welfare or juvenile justice systems, and how have they been treated within them? Have they ever used drugs or contemplated suicide? How do they believe their physical health has been, and do they have any health needs they believe are not being addressed? What do they know about gender transitions and is that something they have thought about? Have they actually begun the transition process? Have they begun to cross-dress? Have they begun puberty blockers or cross-gender hormone therapy, and, if so, where have they obtained their treatment? Have they injected silicone? Have they thought about gender affirmation surgery (sex-reassignment surgery) or other transition-related procedures in the future?

Other questions to consider include, "What have you found on the internet or in various forms of media about transgender people?"; "Do you know any transgender or LGB people?"; and "Who do you have as supports?" Because eating disorders are common among sexual minorities and especially among transgender populations where malnutrition can suppress pubertal progression, it is also important to ask, "Do you restrict your diet, binge and then purge, or use laxatives or make yourself vomit?"

Not all of these questions need to be addressed at the first visit. Follow-up visits should be made to

address these issues on an ongoing basis. The PCP should be aware that the history, beyond providing specific information about the experience and needs of a transgender adolescent, is an opportunity for the PCP to interact with the patient in a comfortable, respectful, and caring manner that validates who the adolescent is as a human being. Many transgender adolescents have never experienced such acceptance before, and providing it is among the most fundamentally important things a PCP can do.

### Physical Examination

The physical examination of children with gender nonconforming behaviors or who express the desire to be other than their anatomic gender is the same as that for other children. A complete examination, including the genitals, should be a routine part of every well-child visit. On occasion, the PCP may observe a child wearing clothes or exhibiting behaviors or interests that are more typical of another gender. These behaviors or interests may or may not relate to the child's gender identity.

Similarly, the content of the physical examination of transgender adolescents does not differ significantly from that of other adolescents. It should be guided by a comprehensive and accurate health history, including sexual and other risk behaviors. The PCP should remember that transgender youths may be heterosexually, homosexually, or bisexually active or not sexually active at all. Many transgender youths hide all public expressions of their gender identity. Some may have already begun the transition process and come to clinic displaying dress, hairstyles, makeup, and mannerisms usually associated with another gender but consistent with their gender identity. Occasionally, transgender patients may wear non-gender-defining street clothes but underwear appropriate for their gender identity. If patients have begun pubertal suppression, they will generally remain at Tanner Stage 2 or 3 and depending on the duration of suppression may eventually show delay in pubertal development relative to their peers. If patients have already begun transition hormone treatment, they may show evidence of breast development (MTF), appearance of facial hair (FTM), and other expected changes of estrogen and testosterone treatment.

PCPs should understand and respect the significant discomfort that many transgender youths have related to their pubertal changes, such as development of facial hair, deepening of the voice, breast development, and menstrual periods, which feel alien to their gender identity. Some MTF-transgender adolescents may tuck their genitals, placing their penis and testes between their legs so they are less visible. Some FTM-transgender youths may wear chest binders or baggy tops to make their breasts less visible. Some may also wear a "packer," which is padding or a phallic-shaped object worn in the front of the underwear or pants to give the appearance of having a penis.

In preparing for the examination, the PCP should discuss the rationale for suggesting the parts of the examination that might be particularly uncomfortable for a transgender adolescent, especially the breast and genital examinations. PCPs should explain that their

intention is to make the examination as comfortable as possible for the patient and to elicit the patient's guidance in how best to accomplish this task. The patient should be informed that they have a right to refuse any part of the examination. The PCP should ask transgender patients what words they would like used in referring to various body parts—for example, *genitals* instead of *penis* or *vagina*. An FTM-transgender patient may prefer the term *chest* rather than *breast*. MTF-transgender patients should be treated the same as other female patients, and FTM-transgender patients like other male patients in conducting the examination. Conducting all comprehensive physical examinations of MTF- and FTM-transgender patients with the patient in a gown and draped appropriately to minimize exposure is best. At the same time, acknowledging that the patient's anatomic features may suggest gender-specific evaluation such as breast, testicular, or pelvic examinations is appropriate. For example, suggesting a pelvic examination for an FTM adolescent with unexplained vaginal discharge or bleeding might be appropriate. Most transgender patients will agree to the suggested examination if the medical rationale is presented in a factual and respectful manner, inviting the patient's questions and input on how to make the examination as comfortable as possible. All aspects of the physical examination should be for the purpose of medical necessity, not to satisfy physician curiosity about possible genital or breast changes related to hormonal or surgical transition therapy. As for all adolescents, a chaperone should be present during a breast, genital or anorectal examination. The gender of the chaperone should be based on patient preference.

### Laboratory Evaluation

The child with gender nonconforming behaviors who has an unremarkable history and normal physical examination requires no special laboratory evaluation. Laboratory evaluation of transgender adolescents should be based on an accurate and comprehensive history, including sexual and other risk behaviors, and physical examination, not on gender identity. Several clinical guidelines provide information on the appropriate laboratory evaluation and monitoring of those patients who elect to begin hormonal transition therapy.

## MANAGEMENT

The goal of care in working with gender nonconforming children and transgender youths is to promote optimal physical, developmental, emotional, and social well-being. The challenge faced by PCPs is to achieve this goal within a context of nonacceptance and stigmatization by many people in society. In this sense, gender nonconforming children and transgender youths have life experiences and needs that are similar to those of LGB youths.

Another challenge faced by PCPs is how to advise and support families of gender nonconforming and gender dysphoric children and youths when there is a considerable lack of professional consensus on appropriate treatment approaches and goals in these age groups. Because there has been insufficient research

in these and related areas, treatment approaches and goals rely in large part on “expert opinion” rather than scientific data. This has allowed a number of different treatment approaches to be proposed, particularly for preadolescent children, that are sometimes based on differing philosophical foundations but very little science. This lack of evidence-based best practice standards can present a dilemma for PCPs and families in trying to decide which of the varying approaches best meets the needs of a particular child. Fortunately, a 2012 issue of the *Journal of Homosexuality* was dedicated to assisting PCPs and parents by offering a comprehensive review of what is known and what has yet to be learned about gender nonconformity and gender dysphoria in childhood, as well as various treatment approaches and their specified goals. It also provided detailed descriptions of a number of well-established clinical programs and identified areas of consensus and disagreement among them. Ethical implications of the various approaches also were discussed. Since most PCPs work in communities without specialized child and adolescent gender clinics, it is imperative that PCPs become familiar with these issues, understand where they themselves stand philosophically on the continuum of treatment approaches, and be willing to reach out to experts at nationally recognized child and adolescent gender centers for consultation as the need arises.

Although relatively little is known about gender nonconformity, cross-gender identity, and gender dysphoria in childhood, the area that is best understood is the likely developmental trajectories of children with gender dysphoria. It also serves as an excellent example of how robust, reproducible research data can result in a greater degree of consensus around certain aspects of treatment approach. We now know, for example, that the dysphoria of most younger children with gender dysphoria does not persist into adolescence. These children are referred to as *desisters*, and their dysphoria usually disappears in later childhood at about age 7 to 9 years. Research has shown that most desisters will go on to self-identify as lesbian or gay during adolescence, and a small percentage will identify as heterosexual. Children with gender dysphoria that persists into adolescence are referred to as *persisters*, and most eventually identify in adolescence and adulthood as transgender. At this point, there is no way to accurately predict which children will end up desisting or persisting in their gender dysphoria. Another unknown is whether treatment aimed at promoting a child’s desistance is effective, or more importantly, ethical. This is among the more disputed aspects related to the treatment of gender nonconforming expression, cross-gender identity, and gender dysphoria in preadolescent childhood. While there is some controversy related to the treatment of transgender adolescents in terms of timing and length of various transition treatments, most clinical experts support medical transition treatments in adolescence and adulthood, such as pubertal suppression, hormone therapy, and eventual gender affirmation surgery. This is because research has shown that most transgender adolescents have a gender identity that will persist into adulthood. Furthermore, there is a robust body of evidence that

demonstrates that transition treatments are safe and lead to significant improvements in physical and emotional well-being. There is no similar body of research definitively supporting a single treatment approach over another in addressing gender dysphoria and gender nonconformity in preadolescent children, thus leading to the confusing and sometimes contradictory choices facing PCPs and the parents and children they are trying their best to support.

Despite controversy, several shared themes can be found across most treatment programs for preadolescent gender dysphoric and gender nonconforming children. Since research findings related to persistence and desistance among children are well-accepted, with an understanding that most gender dysphoric children will be desisters and no longer gender dysphoric as they move into adolescence, it is generally agreed that the appropriate approach is to provide support and counseling to parents and children, but not to provide medical transition treatment in childhood. There is also a widely held view that social transition in terms of living full-time as a child of another gender or use of name and pronouns consistent with inner gender identity should probably be deferred until adolescence. Since so many preadolescent gender dysphoric children eventually desist, many feel that encouraging them to transition socially and then later “de-transition” might cause unnecessary trauma to the child, although there are no research data to support this. Another area of general agreement is that, ideally, support and counseling should be provided to gender dysphoric children and their families by a multidisciplinary team consisting of the PCP, a psychiatrist or other mental health professional, and a social worker. These professionals can be valuable additions to the treatment plan in exploring a child’s or youth’s sense of gender identity, social and academic functioning, family relationships, cultural expectations, and self-esteem. They can help assess and support parents through the process of acceptance and, it is hoped, eventual celebration of their child. They also can address parental fears, concerns, and misconceptions, which likely will change in nature as a child grows older and moves into adolescence. Most treatment programs emphasize that their goal is not to prevent homosexuality or cross-gender identity. Instead, the stated goal for most is to prevent or ameliorate gender dysphoria, recognizing that not all children with cross-gender identity are gender dysphoric.

Despite these common themes among most programs, there are also significant and often controversial differences regarding what “support and counseling” actually mean among varying programs. These often reflect underlying philosophical differences and varying understandings of gender nonconformity and gender identity, their etiologies, and the degree to which they are felt to reflect possible underlying pathology or simply another way of “being” in the world. At one end of the spectrum are programs that are prepared to focus on perceived psychopathology in a child, a parent, or family dynamics that either cause gender nonconforming expression or

cross-gender identity and dysphoria or allow them to persist. Treatment often involves trying to help a child “work through” his or her cross-gender identity with the goal of decreasing gender dysphoria, even if it means engaging in efforts to decrease a child’s desire to be another gender. Parents are asked to put limits on their child’s cross-gender behaviors and to create more opportunities for their child to have interactions with temperamentally compatible same-sex peers, feeling that these kinds of interactions help solidify a child’s appropriate sense of gender consistent with natal sex, and perhaps counteract pathologic influences contributing to the creation or persistence of cross-gender identity. At the other end of the spectrum are those professionals who believe the appropriate approach is to validate and celebrate the unique gender identity of each child, respecting the child’s right to express their gender as they wish, while keeping them safe in an often nonaccepting and hostile world. Most programs working with gender nonconforming and gender dysphoric children fall somewhere in the middle of the spectrum. They tend not to focus on looking for sources of psychopathology as factors contributing to a child’s gender identity or gender dysphoria. Most feel that a good measure of the dysphoria experienced by children and youths comes from the negative responses of family, peers, and community to their cross-gender identity and expression. Therefore, a significant part of providing support to a child is to determine how safe and supportive that child’s environment is and to work with extended families, schools, places of worship, and other settings to ensure that a child is safe and validated in all areas of his or her life. Parents are provided information about gender dysphoria and its possible developmental trajectories, as well as the understanding, skills, and resources to support their child effectively, no matter what their gender identity or sexual orientation might eventually be. Most physicians take a “watchful waiting” approach toward the child, allowing the child to express their gender, although sometimes suggesting certain limits (for example, being allowed to cross-dress at home but not when they go to school). As a child approaches adolescence they are especially watchful for evidence that a child’s gender dysphoria, if present, may persist or desist. If it looks like it may persist then discussions with parents and child about possible future choices related to transition take place (for example, the initiation of pubertal suppression early in puberty). If it seems that the child’s gender dysphoria may desist, then there are other discussions to be had, including considering the possibility that a child may later recognize a lesbian or gay identity, and providing family and child supportive resources in preparation for this possibility.

When faced with such a diverse and often contentious array of opinion and practice, what is a PCP to do when a family arrives in their clinic expressing concerns about their young child’s gender nonconforming behaviors, expressed cross-gender identity, or gender dysphoria? First, it is important to be familiar with the areas of consensus and controversy outlined above. Secondly, it is important to keep in mind

the replacement of the GID diagnosis with gender dysphoria in the *DSM-5*. This means that gender nonconforming expression and cross-gender identity per se are now considered part of the normal spectrum of human diversity. Discomfort and distress over gender should be the focus of concern, and the goal of treatment is to prevent or ameliorate that distress, whether its origins are within a person’s psyche, in their environment, or perhaps both. It is important to remember that the goal of treatment is not to prevent homosexuality, and most physicians would agree that it is also not to change a child’s expressed gender identity. PCPs should be aware of and willing to access local and national resources that can support them in the provision of informed care to these children and youths and their families. If possible, it is very helpful to bring together a multidisciplinary team as described above, to support both the patient and the patient’s family over time, from childhood through adolescence and possibly into adulthood.

It is important to be open with parents about the varying approaches to working with gender nonconforming and gender dysphoric children, and about their underlying assumptions and goals. It is also important for PCPs to let parents know where they are on the spectrum of professional opinion about the appropriate treatment approach to these children and their families. PCPs or other team members should open the opportunity for a discussion of parental concerns, fears, and degree of comfort related to their child’s gender identity and expression. They should also be asked what their hopes and expectations around treatment might be. Parents should be informed clearly that the goals of treatment are to prevent or diminish a child’s distress around gender, but not to change their gender identity or sexual orientation. Often parents fear that their child might someday be lesbian or gay, and may or may not have thought about the possibility of their child being transgender. The PCP should gently remind parents that any child might be gay, lesbian, bisexual or transgender, and let them know of the medical profession’s position that all these possibilities are considered normal developmental outcomes, while recognizing that not all segments of society yet agree. The PCP should also share, in lay terms, what is known about the developmental trajectories of children experiencing gender dysphoria—that in adolescence many do come to realize their lesbian or gay identities, while a much smaller number are transgender. Over time, as a child gets older, this issue should be revisited, offering parents an opportunity to share their thoughts or concerns and allowing the PCP to correct misconceptions and connect parents, children, and youths to supportive resources.

Above all, PCPs should remind parents of the importance of expressing their unconditional love for their child and refraining from comments or actions that demonstrate disapproval of their child’s gender expression or identity. The Family Acceptance Project at San Francisco University has conducted research demonstrating the important role that parents play keeping their lesbian, gay, bisexual, and transgender children healthy and safe through the provision of acceptance and love. The PCP should share this understanding with

all families, and provide them the skills and resources to accept and support their children no matter what their gender identity or sexual orientation might be.

The following sections continue the discussion by focusing on how PCPs can recognize and address the needs of transgender adolescents.

### Physical Well-being

Gender nonconforming children and transgender youths face the same health issues as other young people. The health care they receive should be based on a comprehensive history, physical examination, and evaluative studies, not on their gender expression or identity. Nevertheless, the PCP should recognize that these children and youths often grow up in hostile environments that may have a negative effect on their physical well-being. Among these negative effects are the physical sequelae of substance use, poor nutrition caused by homelessness or disordered eating, unprotected sexual behaviors, self-harm, injuries from physical and sexual victimization, and hormonal or surgical transition treatments accessed outside of health care settings.

### Developmental, Social, and Emotional Well-being

In most ways, children with gender nonconforming expression and transgender youths are exactly the same as their peers. They have the same needs for protection, nurturance, and love and the same hopes and dreams for the future. They grow up in the same families and communities and attend the same schools and places of worship. Similar to other children, they face the fundamental task of achieving a sense of identity that integrates all aspects of who they are, including their sexual orientation and gender identity. This integration of sexual and gender identity, accompanied by a growing sense of comfort with that identity, is essential for the optimal health and well-being of each child and adolescent.

However, the experience of growing up as a child with gender nonconforming expression or as a transgender youth is different in several important ways. Unlike their peers, these young people face an often lonely and sometimes frightening journey of self-discovery, attempting to understand 2 of the most fundamental aspects of who they are as human beings—their gender identity and their sexual orientation. Some of these children will recognize, often at a young age, that their inner sense of being female, male, or another gender differs from the gender that was assigned to them at birth. Some children and adolescents accommodate themselves to this growing awareness. Most, however, experience significant confusion and distress, wondering what their feelings mean and uncertain of who they are. Growing up in a society that believes that a person is either male or female and that gender expression and identity must strictly reflect biologic sex undoubtedly intensifies their sense that something inside them has gone wrong. Many of these individuals become filled with an overwhelming mix of confusion, shame, anger, self-hatred, and despair. It is important to remember that most gender-dysphoric children eventually self-identify as lesbian, gay, or bisexual and no longer experience

gender dysphoria as adolescents. Being lesbian, gay, or bisexual in an often-disapproving society may bring its own distinct set of developmental challenges.

The PCP's role as educator and counselor is as important as that of medical physician in caring for gender nonconforming children, transgender youths, and their families. The PCP should avoid assumptions based on stereotypes and listen carefully to understand each patient's unique experience and needs. In general, the counseling of nonconforming and transgender youths will address 6 areas: (1) self-acceptance and validation of gender expression and identity, (2) safety, (3) connectedness to supportive others, (4) self-disclosure or *coming out*, (5) healthy relationships and sexual decision making, and (6) optimism for the future. Addressing each of these areas is essential in ensuring their healthy development. These should be addressed over time and not all at an initial presentation or single visit.

### Self-acceptance and Validation

The PCP can play an important role in countering the effects of disapproval and the pathologizing of gender nonconforming expression and identity. For the gender nonconforming child, the PCP should state that although being different in this society can be painful, the child's gender nonconforming behavior can be healthy for that child. For transgender youths, the PCP should acknowledge the controversy around the use of gender dysphoria as a diagnostic category. PCPs should present being transgender as part of the tapestry of normal human identity and clarify that the primary issue of concern is distress that can often come from having a transgender identity in a society that is unaccepting. This validating reassurance of healthiness and normalcy is perhaps the most powerful statement a PCP can make to gender nonconforming children and transgender youths and their families.

A growing number of older gender nonconforming children and transgender adolescents know a significant amount about gender, gender identity, and gender expression. Many have done extensive research on the Internet, accessing YouTube videos and Web sites that are easily searchable, or connecting with other gender nonconforming and transgender youth on social media. Others, however, continue to be very isolated and know little or nothing about the nature and meaning of their emerging sense of identity. Therefore, the PCP should conduct an initial inquiry into what the youth knows and has seen or read, and focus on correcting misconceptions, providing validation, and supporting empowerment. Gender nonconforming children can be reassured that many ways exist of being a boy or a girl and that their way is one of these many ways. They can also be told that some children feel more like a girl inside and some more like a boy, or perhaps another gender, and that however they feel in terms of gender identity is all right. Transgender youths should be provided information on sexual orientation, gender identity, and what it means to be transgender. Some of these adolescents may go through a period of confusion, not knowing whether they are gay, lesbian, bisexual, straight, transgender, or a combination of these. The PCP should inform the

adolescent that such uncertainty is normal and that over time they will have a clearer understanding of who they are. The PCP may also provide brochures to adolescents facing issues of gender identity or refer them to supportive Web sites.

Ethnic and other minority youths who are transgender may have an especially difficult time. The PCP should discuss these issues with their patients openly and connect them to appropriate supportive resources within their communities and online.

### **Safety**

Because gender nonconforming children and transgender youths endure higher rates of physical and sexual assault, harassment, discrimination, and social rejection, PCPs should ask gender nonconforming children and transgender youths about their safety in their home, school, place of worship, and broader community. If harassment or other harmful treatment is acknowledged, then the PCP should work with the youth and family to identify and implement appropriate strategies to end the violence. Many of these children and youths feel shame and are afraid to advocate for their own safety. They may think they deserve the harm inflicted on them, or they may simply accept that this is the way the world is. The PCP should tell children and adolescents that they do not deserve such treatment and that they should expect and demand safety and respect from everyone in their lives and in all settings. Because gender nonconforming children and transgender youths have so few advocates, the PCP should offer to join with them in approaching every venue in which they experience violence, including the home and school, to work out a plan to end violence immediately and completely. Parents, PCPs, teachers, and others should also work together to ensure that schools and other community organizations create and implement policies and practices that ensure respectful treatment and appropriate accommodations for these children. The state of Massachusetts, for example, has developed a detailed policy statement about the responsibilities of schools to accept and support gender nonconforming and transgender students, which can serve as a model for other states. (See Tools for Practice at the end of this chapter.) Many states also have specifically designated offices, often within state departments of education, to combat bullying and harassment, including that specifically based on gender identity and expression. If necessary, the PCP should call on the state child welfare services office or advocacy organizations such as the American Civil Liberties Union to join in the effort to keep these young people safe.

### **Isolation**

Because gender nonconforming children and transgender youths experience profound isolation and loneliness, their physical and emotional health may be compromised. PCPs should address the issue of isolation by giving accurate information about gender expression and gender identity. They should provide supportive and reassuring counseling, or they should refer the child or adolescent to colleagues who have the time, comfort, and expertise to

provide them accepting and supportive care and counseling. PCPs should connect these children and youths to local community resources such as support groups and other youth programs. Children, youths, and families who do not have access to local programs should be informed about national organizations and Web sites created specifically for gender nonconforming children, transgender youths, and their families (see Tools for Practice). PCPs can also point out positive gender nonconforming and transgender role models in the community or nationally. In certain circumstances, it is appropriate for transgender PCPs to present themselves as role models to transgender youths and their families.

### **Self-disclosure and Coming Out**

Transgender adolescents often reach a point in their development at which they feel a strong urge to disclose their gender identity to others. Transgender youths often have a history of gender nonconforming expression as children. Therefore others may have already assumed or sensed that they may be transgender or lesbian or gay. Some transgender youths, however, successfully conceal their gender identity, either by adapting their gender expression to fit societal expectations consistent with their biologic sex or by labeling themselves or allowing others to perceive them as gay or lesbian. The process of disclosure to family and friends is often emotional and traumatic. Transgender youths who disclose their gender identity (come out) risk condemnation and rejection by family and peers. Therefore, coming out should be considered carefully, weighing the risks and benefits. It is sometimes suggested that if an adolescent expects a negative response from parents, then the adolescent should wait to disclose until legally and financially independent. However, many adolescents think that continuing to live a lie is intolerable and harmful to their self-esteem, and they come out earlier. A PCP should never reveal an adolescent's gender identity to parents without permission unless imminent risk of harm exists. A PCP can play an important role in the process of disclosure by helping adolescents decide whether they are ready to come out to family or friends and helping them choose an appropriate time, place, and approach for disclosure. PCPs who feel they do not have the skills to provide such counseling effectively should refer to or collaborate with a therapist who can guide the teen and support the family through the coming out process.

### **Relationships and Sexual Decision Making**

Most transgender youths have difficulty in meeting other transgender adolescents to establish friendships and share mutual support. PCPs should help connect transgender youths to local LGBT teen support groups and LGBT-supportive programs in the community, if they exist. This task can be accomplished ethically without parental notification. PCPs can suggest national telephone hotlines or Web sites where transgender youths can receive accurate information and supportive counseling and can communicate with other transgender youths (see Tools for Practice). If these options are not available, then the PCP can serve

as a supportive and reassuring lifeline until the adolescent is old enough to become independent and possibly move away to attend school or work in a community more accepting of transgender people.

Transgender adolescents may be heterosexual, homosexual, or bisexual in their attractions and behaviors. Given the prevailing societal disapproval of transgender individuals, however, many transgender youths are afraid to reveal their gender identity to those with whom they might be interested in establishing a relationship. Therefore, some transgender youths find that their only options for exploring emotional and physical intimacy are through anonymous sexual encounters on the streets, in parks, or through Internet hookups. In addition to being potentially dangerous, these encounters are often accompanied by feelings of shame and degradation, which are harmful to an adolescent's sense of identity and self-worth. That many transgender youths are eager to engage in the typical courting practices of adolescence, which normally take place in safer and more affirming circumstances, is evidenced in the great popularity of LGBT youth proms and other social gatherings in a growing number of communities across the United States.

Transgender youths who are in relationships face many of the same questions as their nontransgender peers: "Am I in love?" "What do I want from a relationship?" "Do I really want to be in this relationship?" "How do I know if this is a good relationship?" "How do I get out of this relationship?" In addition, transgender youths face the exceedingly difficult questions of how and when to tell their potential boyfriend or girlfriend about their gender identity. A transgender-supportive PCP or therapist can help adolescents reflect on and find answers to these questions.

As with other adolescents, many transgender youths know little about sexuality and how to make healthy sexual choices. Abstinence is always the appropriate option for adolescents who do not feel ready for a sexual relationship. Transgender adolescents should understand that when they are ready for a sexual relationship, they can expect to lead healthy and fulfilling sexual lives. All adolescents who have decided they are ready for a sexual relationship should be advised to limit their number of sexual partners and avoid mixing sex and alcohol or drugs so as to reduce their risk for infection, trauma, and sexual assault. Transgender youths, like other adolescents and depending on the sexual behaviors they engage in, are at risk for unplanned pregnancy and should be counseled on contraception. Not only could pregnancy lead to medical risks but it often can be extremely psychologically traumatizing to a gender nonconforming or transgender youth. Safer sex practices related to oral, vaginal, and anal sex should be reviewed in detail. Transgender youths should also be aware that *no* always means *no* in negotiating sex, and any forced or coerced sexual experience represents sexual assault.

### **Optimism for the Future**

PCPs should not only focus on the risks that transgender youths face, but also identify specific strengths that have allowed them to survive and sometimes thrive in the face of an often hostile environment. They should also challenge the belief of many transgender

adolescents that their futures will be significantly limited by their gender identity. Although some communities are more accepting of transgender people than others, many transgender adults lead happy, healthy, and productive lives. Although growing up transgender is often challenging, the future should be seen as hopeful and exciting.

### **TRANSITION CARE**

Transition represents the emotional, psychological, social, physical, and legal processes transgender persons experience to assume a body and gender role consistent with their gender identity. The transition process often begins in childhood and continues through adolescence into adulthood. Pubertal suppression, hormone therapy, and surgery are often the final medical steps in this process. PCPs play an essential role in facilitating the patient's transition from female to male, male to female, or perhaps to another gender. They often have known their gender nonconforming and gender dysphoric patients since early childhood. As puberty approaches and it seems that gender dysphoria may persist into adolescence, they are in an advantageous position to provide patient and parents with detailed and accurate information about the nature and timing of transition, its limitations and benefits, and the choices that lie ahead. It is also important to share with families that, just as there is significant controversy around the understanding and management of gender dysphoria and gender variance in childhood, there is also controversy around certain aspects of the provision of medical transition care from early puberty through adolescence. This understanding is essential in order for patients and parents to give informed consent to treatment. At the same time, it is imperative for the PCP to be clear about where she or he stands within the spectrum of opinion on the medical management of transition, including pubertal suppression, hormonal treatment, and gender-affirmation surgery.

The PCP has an important role in helping patients and families identify possible natural transition points for initiating hormone therapy, such as when a patient is changing schools (for example, from middle school to high school) or a family is planning to move to a new home and neighborhood. Whether or not such transition points are identified, it is important that the PCP work with school personnel before transition begins, educating them about what it means to be transgender and the social and psychological benefits of transition. The potential risk of harassment by other students or by school staff should also be addressed. In order to ensure both respectful treatment and safety in the school setting, the PCP should advocate for the development of an IEP or other formal assurance that the transgender student's preferred name and pronouns will be used in all school settings, both inside and outside the classroom and whether the student is present or not, and that appropriate restrooms and changing rooms are identified and accessible.

In addition to facilitating and monitoring social and psychological aspects of transition, PCPs are playing an increasingly central role in the initiation and management of physical transition, including both pubertal suppression and hormonal therapy.

Many PCPs still feel they do not have the training, experience, or time to do so effectively. Therefore, they refer their patients with significant gender nonconformity or gender dysphoria to gender specialists and other colleagues whom they feel have greater expertise in assessing gender issues and providing transgender care. At the same time, they retain their role as PCP and provider of a medical home. Many larger communities have endocrinologists and adolescent medicine, family practice, and internal medicine physicians, as well as mental health physicians, who are experienced in providing medical care and counseling to gender dysphoric youths considering transition. Such physicians often can be located through local LGBT community centers or national organizations such as the Gay and Lesbian Medical Association. Many PCPs, however, practice in smaller communities with few or no physicians with such expertise. These physicians should reach out to regional or other gender experts, through telemedicine and other means, to request their guidance in the evaluation and management of children and youths experiencing significant gender nonconformity or gender dysphoria. Thus, through necessity, many PCPs have become experts on transgender care. They recognize that for most gender dysphoric youths entering puberty, the provision of transition-related treatments such as pubertal suppression and hormonal therapy (outlined below) is not elective but instead represents a standard of care, with the early institution of treatment predicting optimal improvement in both physical and psychological well-being.

Guidelines are available to help PCPs and other physicians facilitate the transition process. WPATH in 2011 published the seventh edition of *Standards of Care for Transsexual, Transgender, and Gender Non-conforming People*, which is considered to be among the most authoritative guides to providing medical and mental health transition counseling, treatment, and support. The Endocrine Society also has developed detailed clinical practice guidelines on hormonal transition treatment for transgender adolescents and adults. In addition, several health centers experienced in providing comprehensive transgender health care have developed their own clinical guidelines. These latter guidelines often approach transgender care based on an informed-consent model, which is premised on a belief in the ability of patients (and if a minor, their parents as well) to determine their own transition path if provided complete and unbiased information about transition choices and their benefits and limitations. This model differs markedly from the traditional approach to transition care, including those represented in earlier versions of the WPATH standards of care, which presented a very prescriptive and linear path to transition. Under these earlier standards, transition was presided over by medical and mental health gatekeepers who could decide who was eligible for transition treatments, as well as the nature, sequence, and timing of those treatments. The latest edition of the WPATH standards of care differs significantly from previous versions. It is much more patient centered and allows for a flexible approach in which recommendations related to transition care may be modified on a case-by-case basis in order to

address a patient's specific needs and circumstances. The ultimate goal of the current WPATH standards of care is to reduce gender dysphoria and maximize physical and psychological well-being. It explicitly emphasizes that efforts to change an individual's gender identity or expression are considered unethical.

Regarding physical interventions for adolescents considering transition, WPATH suggests an approach consisting of 3 stages: (1) fully reversible interventions, using gonadotropin-releasing hormone (GnRH) analogs in early puberty to suppress estrogen and testosterone production, thereby delaying the progression of puberty; (2) partially reversible interventions, consisting of hormone therapy to masculinize or feminize the body; and (3) irreversible interventions such as gender-affirmation surgery, generally occurring in adulthood. WPATH advocates a staged approach in order to allow the adolescent and parents time to adjust to one stage before moving on to the next. The involvement of a multidisciplinary team to support the adolescent and family through the significant changes of physical, psychological, and social transition is highly recommended, with the understanding that the role of each team member is to facilitate the process of timely transition and not to stand as a gatekeeper obstructing the path to receiving appropriate care, as has occurred in the past.

Despite WPATH's staged model of transition care, it is important to recognize that the path of transition is not the same for everyone. Some individuals are satisfied to live their lives consistent with their gender identity in a social sense but have no urge to initiate hormone therapy or undergo surgery. Others seek hormone treatment but feel that surgical alteration of their bodies is unnecessary. Still others may choose partial surgical gender reassignment; for example, many FTM transgender individuals choose mastectomy but not genital reconstruction. In addition, the transition process is not necessarily a linear one. Some individuals move back and forth between feelings of being more feminine or masculine and may present themselves differently to the world at different times in terms of gender role and expression. This fluidity of identity should be expected and supported by the PCP.

### Pubertal Suppression

Pubertal suppression has become the standard of care for children entering puberty with persistent gender dysphoria, and it is advocated by both WPATH and the Endocrine Society. Puberty is suppressed through the administration of GnRH analogs, very similar to the treatment of precocious puberty in younger children. Pubertal suppression as treatment for gender dysphoria represents an off-label use of this medication. GnRH analogs suppress the secretion of luteinizing hormone (LH) from the pituitary, resulting in suppressed levels of testosterone and estrogen, thereby postponing the development of secondary sexual characteristics. One proposed benefit of pubertal suppression is that it allows an adolescent additional time to better understand his or her gender identity and with increasing maturity be able to make more informed decisions about whether to proceed with gender transition or not. A second benefit is that pubertal

suppression can prevent or postpone the emotional trauma that can accompany the development of secondary sexual characteristics reflecting natal sex for most transgender youths, resulting in decreased gender dysphoria. A third benefit is that pubertal suppression prevents the development of secondary sexual characteristics that often makes later physical transition much more difficult. Hormonal therapy is much more effective in bringing about desired physical changes if the undesired pubertal changes reflecting natal sex have not taken place. Suppression of unwanted pubertal changes may also decrease the need for more invasive interventions later, such as breast surgery, electrolysis, and tracheal shaving.

For a child experiencing persistent or emerging gender dysphoria, pubertal suppression should be initiated when the first signs of puberty appear (which may occur as early as age 9). Suppression should continue until the adolescent is able to confidently specify his or her gender identity. If an adolescent decides that his or her gender identity is consistent with natal sex, pubertal suppression is ended and puberty allowed to proceed. The hormonal influences of suppression are completely reversible with no compromise to subsequent pubertal development. If an adolescent confirms a transgender identity, pubertal suppression is ended and cross-gender hormonal treatment is begun.

During pubertal suppression, the involvement of a supportive pediatric endocrinologist is recommended. Research on the use of GnRH analogs suggests the possibility of decreased bone mineral density in some patients during suppression treatment. However, current research suggests that children who have been on suppressive therapy catch up on bone growth once they progress through puberty or are started on cross-gender hormone therapy. Suppression therapy may also lead to irregular menses in biologic females, particularly if started later in pubertal development. An endocrinologist can help address these issues and can monitor attainment of gender-appropriate height, making appropriate adjustments to treatment as necessary. The few potential risks of suppression treatment must be weighed against the growing body of research documenting the positive outcomes on physical and psychological well-being resulting from the use of pubertal suppression in the management of gender dysphoric youth in early puberty and adolescence.

Gender dysphoric youths whose natal sex is male should be informed, along with their parents, that pubertal suppression could result in insufficient penile tissue if later penile-inversion vaginoplasty is desired. However, skin grafts and colonic tissue may be used instead. PCPs should also have detailed discussions with patients and their parents about the effects of both pubertal suppression and cross-gender hormone therapy on future fertility. Youths who receive only pubertal suppression treatment should progress to full fertility once pubertal suppression is discontinued and pubertal development resumes. Those who move from pubertal suppression directly to cross-gender hormone treatment likely will experience some degree of impaired fertility. Some patients may choose to have a hormone-free interval between pubertal suppression and the initiation of cross-hormone therapy in order to permit

collection of sperm and oocytes for cryopreservation. Others have interrupted cross-gender hormone therapy later in life for the same purpose. The important thing is that this essential conversation take place, and that patients and their families are made aware of fertility experts that they may turn to for further consultation. Finally, families should be informed that pubertal suppression treatment is expensive and may not be covered by some insurance plans, although this likely will change as such treatment increasingly is recognized as a standard of care.

The primary controversy related to pubertal suppression therapy relates to when it should be started. Gender specialists agree that for children who have long-standing or emerging intense gender dysphoria at the onset of puberty, pubertal suppression should be initiated early. While some guidelines suggest beginning therapy at Tanner Stage 2 or 3, many advocate beginning treatment with the first physical or hormonal evidence of puberty, early in Tanner Stage 2.

### Hormone Therapy

The offering of hormonal therapy, like pubertal suppression, represents a standard of care for adolescents experiencing gender dysphoria. A number of protocols are available that address the evaluation and hormonal treatment of transgender adolescents. There is uniform agreement across protocols on the appropriateness of hormonal treatment for transgender adolescents, supported by research showing the significant benefits of hormonal transition in terms of both physical and psychological well-being. Certain aspects of these protocols, however, continue to be quite controversial. The most significant among these reflects a debate among physicians about the appropriate age for initiating hormonal therapy. Historically, the age of 16 was most often cited, accompanied by a belief that a 16-year-old would be better able than a younger adolescent to make informed, mature decisions around treatment that could lead to irreversible physical changes. In fact, age 16 was initially recommended solely because the age of majority in the Netherlands, where most early treatment protocols were developed, was 16, and represented the age at which adolescents in that country could consent to their own care. The latest edition of WPATH's standards of care as well as the recommendations of others working in the field of transgender health allow for flexibility in determining the age of hormonal treatment initiation, advising that such decisions should be made on a case-by-case basis, with age 16 set only as a guideline and with allowances made for earlier initiation. In fact, many families and children seek care much earlier than age 16, and many centers initiate hormone therapy much earlier than 16 and sometimes as young as age 12. These centers see no reason to delay treatment unnecessarily, because the trauma of experiencing puberty reflecting natal sex or being told to wait for years in a suspended peripubertal state as peers continue to develop, is significant, and may even be life threatening. PCPs should discuss these issues openly with families and youths, considering the question, "For this particular child, what is the rationale for suppressing puberty for 3 to 5 years? Does this child in fact display uncertainty regarding his or her gender identity that dictates waiting

this long to end suppressive treatment or initiate hormonal therapy?”

While many centers operate under a belief that mental health support is an essential component of transition, it should not delay or become a barrier to accessing appropriate and timely treatment. WPATH's standards of care state directly that “refusing timely medical interventions for adolescents might prolong gender dysphoria and contribute to an appearance that could provoke abuse and stigmatization. As the level of gender-related abuse is strongly associated with the degree of psychiatric distress during adolescence... withholding puberty suppression and subsequent feminizing and masculinizing hormone therapy is not a neutral option for adolescents.”

### **Male-to-Female Hormone Treatment**

Estrogen is the mainstay of MTF-transgender hormone therapy. For adolescents, most physicians prescribe estrogen sublingually or transdermally, to avoid first-pass metabolism. Protocols also cite oral and injectable forms as options. For transgender individuals, many of the “side effects” of estrogen therapy are in fact desirable effects. Expected changes include breast development, softening of skin, increase in subcutaneous fat and its redistribution to the thighs and buttocks, diminished body hair, fewer erections, and testicular atrophy. Patients may also experience decreased libido, weight gain, and emotional changes. Some of these changes may be irreversible, continuing even after possible discontinuation of treatment. Fertility will be impaired while on estrogen therapy and possibly even if estrogen treatment is discontinued. This should be discussed openly with patients and their parents, as should the option of cryopreservation of sperm if desired. Estrogen treatment is generally safe in adolescents. Although PCPs should be aware of the precautions generally noted for estrogen therapy, including the possibility of blood clots in high-risk populations such as smokers, medical contraindications to estrogen treatment in adolescents are rare. Antiandrogens, such as spironolactone, finasteride, and GnRH analogs, are routinely added to the regimen to suppress the action of endogenous testosterone, augment breast development, and soften facial and body hair. Gonadectomy serves a similar purpose although generally is not considered until age 18 or older as part of gender affirmation surgery.

### **Female-to-Male Hormone Treatment**

The FTM transition is facilitated through the use of testosterone administered through injection, patch, or topical gel. Testosterone treatment is generally safe in adolescents. Among the potentially desirable “side effects” of testosterone treatment for these patients are increased facial and body hair, clitoral enlargement, vagina atrophy, cessation of menses, male pattern baldness, deepening of voice, decreased fat mass, increased muscle mass and strength, a more masculine body shape, increased weight, more prominent veins, coarser skin, and mild breast atrophy. Patients may also notice increased acne, mood changes, and increased libido. Some of these changes may be irreversible. Fertility will likely be impaired during testosterone treatment, although it may return if treatment is interrupted. PCPs

should discuss this openly with patients and their families, and should also discuss options for cryopreservation of oocytes before treatment is begun.

### **Other Treatments**

Some transgender individuals will seek other treatments to facilitate physical and psychosocial transition to their appropriate gender. Often these treatments will occur after the adolescent years, partly because these procedures are expensive and not yet covered by many insurance plans. Because many of these treatments involve irreversible changes, most protocols recommend deferring them until at least age 18, especially those that represent gender affirmation surgery. MTF-transgender individuals may seek reconstructive surgery, including penectomy, orchiectomy, vaginoplasty, clitoroplasty, vulvoplasty, breast and gluteal augmentation, tracheal shaving, and facial reconstruction. Electrolysis or other hair-removal procedures may be sought. Silicone injections also may be sought to obtain a more feminine body contour. FTM-transgender individuals may seek chest reconstruction surgery, hysterectomy, oophorectomy, phalloplasty, and other genital reconstruction. Both MTF and FTM individuals may seek voice therapy and professional guidance in how to present themselves as male, female or another gender through body language, facial expression, gait, posture, and mannerisms. Although these surgical, cosmetic, and other procedures often take place after adolescence, discussing these options and their benefits and limitations and making appropriate referrals should be part of the PCP's anticipatory guidance of transgender youths.

## **PARENTS**

Parents who come to recognize their child's gender nonconforming behavior or transgender identity may experience a variety of emotions: confusion, fear, sadness, concern, embarrassment, guilt, anger, or disgust, but also acceptance and celebration. These feelings should be discussed openly and with compassion. Many parents fear for their child's safety and happiness. Many of them fear that their child may eventually self-identify as lesbian or gay. In many instances these concerns and fears are not raised on visits to the PCP or are referred to only indirectly (“My son is a sensitive child,” or “My daughter is definitely a tomboy”). The PCP should be sensitive to any cues of parental worry about gender nonconformity and ask parents simply, “Do you have any concerns about your child's behaviors?” or even better, “Have you had any concerns that your son's [daughter's] behaviors or interests are more feminine [masculine] than other children's his [her] age?” Most concerned parents, although perhaps embarrassed, are relieved to have such a discussion. The PCP's primary role in working with parents is to help them understand and celebrate their gender nonconforming child and support them in their efforts to keep their child happy, healthy, and safe.

Parents should be referred to Web sites, books, brochures, and media resources geared to parents of gender nonconforming children.

Parents should be assured that with love, validation, and support their children should grow up to be happy, healthy, and productive adults, no matter what their gender expression, gender identity, or sexual

### **BOX 156-1 Children's National Medical Center Outreach Program Guidelines for Parents of Gender-variant and Transgender Youth**

- Love your child for who your child is. Love, acceptance, understanding, and support are especially important when peers and society are often intolerant of difference.
- Question traditional assumptions about gender roles and sexual orientation. Do not allow societal expectations to come between you and your child.
- Create a safe space for your child, allowing your child always to be who the child is, especially in the child's own home.
- Seek out socially accepted activities (sports, arts, hobbies) that respect your child's interests while helping your child fit in socially.
- Validate your child and your child's interests, supporting the idea that more than one way exists to be a girl or boy. Speak openly and calmly about gender variance with your child. Talk about these subjects in positive terms, and listen as your child expresses feelings of being different.
- Seek out supportive resources (books, videos, Web sites, support groups) for parents, families, and children.
- Talk about gender variance with other significant people in your child's life, including siblings, extended family members, babysitters, and family friends.
- Prepare your child to deal with bullying. Let your child know that he/she does not deserve to be hurt. Be aware of behaviors that suggest bullying may be occurring, such as school refusal, crying excessively, or complaining of aches and pains.
- Be your child's advocate. Expect and insist on acceptance, respect, and safety wherever your child is. Parents may need to educate school staff and others about the special experience and needs of gender-variant children.

### **BOX 156-2 Children's National Medical Center Pitfalls to Avoid as Parents of Gender-variant and Transgender Youth**

- Avoid finding fault. No blame exists. Your child's gender variance came from within, not from you as parents. Blame will get in the way of enjoying your child.
- Do not pressure your child to change, because this will cause much pain and harm.
- Do not blame the victim. Do not accept bullying as *just the way things are*. No one has the right to torment or criticize others because they are different.

orientation might be. The National Children's Medical Center has developed guidelines to help parents in their provision of support for their children.

Box 156-1 lists ways parents can support their child, and Box 156-2 lists pitfalls parents should try to avoid.

## **ADVOCACY**

Because of their expertise and position of respect, PCPs are in an advantageous position to advocate on behalf of children with gender nonconforming behaviors, transgender youths, and their families. PCPs should encourage parents, siblings, and extended family to accept and love these young people unconditionally. The PCP should also be willing to meet with school personnel, child and youth welfare program staff, and others to share information about gender nonconformity and transgenderism. Because schools are a major part of a child's or adolescent's life, and because they are often the site where significant harassment and bullying of gender nonconforming and transgender youths take place, it is especially important that PCPs

provide advocacy at all levels of local educational systems. This includes advocacy for the adoption of antiharassment policies specifically addressing harassment based on gender identity and expression as well as sexual orientation. It also includes advocating for mandated training of teacher and social service providers and policies that ensure that transgender youths are safe and treated respectfully, such as through the use of preferred names and pronouns, designation of appropriate bathrooms and changing rooms, and allowing a student to participate in graduation ceremonies and other activities based on gender identity rather than natal sex.

For PCPs seeking to advocate for societal change, encouraging the development and implementation of policies, procedures, and programs that recognize and respect the individuality of these children and youths and address their special needs for validation and safety is essential. The PCP may also provide testimony at official meetings and hearings on proposals to add gender identity and expression to laws and school policies prohibiting discrimination, bullying, and harassment. The PCP may also advocate for the inclusion of meaningful medical school, residency training, and continuing medical education curricula on the life experience and health needs of children with gender nonconforming behaviors and transgender individuals and how to meet these needs in a respectful and effective manner. Finally, the PCP should encourage professional organizations to develop policy statements and clinical guidelines to support them in their work with these young people and their families.

## **WHEN TO REFER**

Refer to a child behavioral, adolescent, or gender specialist whenever a child or adolescent

- Shows significant gender nonconforming behaviors, particularly if they are concerning to

parents or have resulted in rejection or mistreatment by family members, peers, or others. Ideally, referral will be made before possible dysphoria arises.

- Shows signs or symptoms of gender dysphoria, including expression of dissatisfaction or distress related to their birth-assigned gender or insistence that they are of another gender.
- Refer to a child and adolescent psychiatrist or other mental health professional whenever a child or adolescent.
- Experiences persistent or recurrent depressed or anxious mood that interferes with function.
- Has acute or recurrent suicidal ideation or self-injury.
- Evidences isolation from peers or family members.
- Engages in substance use or other high-risk behaviors.

It should be noted that referrals for therapy to change an adolescent's gender identity or expression are considered unethical.

### Medical Decision Support

## Chapter 157

# HEADACHE

Jack Gladstein, MD

For a pediatrician, a chief complaint of headache can be daunting. Although the outcome is most often benign, the worry of both the parent and the clinician centers on the fear of missing a tumor or other serious condition. Given the constraints of time in a busy office, an efficient but caring approach will allay the anxiety of both the family and the physician.

### CLINICAL APPROACH

#### Part 1: Establish the Right Pattern

All headaches in the pediatric age group fall into 4 patterns as described by Rothner (see Figure 157-1). The most common pattern is called *acute and recurrent*, characterized by periods of normalcy between attacks. Severe attacks accompanied by autonomic symptoms (nausea/vomiting, photophobia and/or phonophobia) ensure the diagnosis of migraine. Milder attacks are called *tension type* headaches. The migraine patient may also have milder tension type headaches, and because these headaches still respond to triptans the distinction in a migraine patient is basically irrelevant. Children who *never* get autonomic symptoms but have this pattern have pure tension type headache, and do not respond to triptan medications. In children, location of the headache is less important diagnostically than in adults. Ninety percent of migraine in the pediatric age group is bilateral. Pain can be under the eyes or even in the neck area. If the pattern is still acute and recurrent, and there are

autonomic symptoms, the diagnosis is migraine. Most children and teens have migraine without aura. Children who have migraine with aura often describe wavy lines at the periphery of their vision.

In the context of headache, a *simple acute headache* is less of a diagnostic dilemma. It can be caused by meningitis, encephalitis, systemic viral or bacterial infection. Subarachnoid hemorrhage features a severe headache that gets to full force instantly. Patients describe feelings of being shot or punched in the head. There can sometimes be accompanying fever or neck stiffness. The speed of headache onset is what is important here.

The pattern of *chronic progressive headache*, where symptoms get worse and worse over weeks, should alert the physician that a tumor or other serious pathology looms. Pain is often worse in the morning and gets a little better as the day goes on. Systemic or neurologic signs and symptoms further add to the worry. Posterior fossa tumors are often accompanied by wobbly gait. Frontal tumors may present with unilateral weakness. Tumors of the pituitary area manifest with changes in visual acuity or problems with growth; adolescent girls may have secondary amenorrhea.

*Chronic nonprogressive headache* either evolves from a previous headache pattern or presents without previous headache history. In *transformed* or *chronic migraine* there is a history of prior acute intermittent headache accompanied by autonomic symptoms. Over time, the pain has become almost daily, with intermittent spikes in headache resembling bad migraine. In *chronic tension type headache* (CTTH), there is a history of episodic tension type headaches. With no history of migraine attacks, triptans have no role in this condition. In *new daily persistent headaches* (NDPH), the daily headache comes out of nowhere, often after a viral syndrome or mild head trauma. Whereas TM or CTTH responds well to a multidisciplinary approach, NDPH is more of a

**Figure 157-1** All headaches fit in this diagram. The severity of the headache is on the Y axis, and time measured in days is on the X axis. (From Rothner AD. *The evaluation of headaches in children and adolescents*. Semin Pediatr Neurol. 1995;2(2): 109–119, with permission from Elsevier.)

troublesome problem, often puzzling even the most experienced headache specialist. Patients with the chronic nonprogressive pattern of headache require imaging because there is no return to normalcy between attacks.

### Part 2: Establish Disability With 2 Questions

Since an acute headache is not, from the point of view of headache, a diagnostic dilemma, and chronic progressive headaches warrant timely evaluation for serious intracranial pathology, the issue most commonly facing the physician is how to proceed artfully and efficiently to manage most patients who come to attention with headaches. For both intermittent migraine and chronic daily headache the first priority is to assess how disabled the child is, using as measures *absenteeism* and *presenteeism*. Absenteeism refers to the number of days missed from school, work or after-school activities. Presenteeism refers to days when, although present, the child cannot learn or fully participate because of headaches. Worsening of school grades can result either from the child being absent or, if present, having performance adversely affected by headache. The more disabled the child is, the heavier the required intervention.

Having properly categorized the headache from the initial history, decided whether or not serious underlying pathology is a consideration, and assessed how disabling the headaches are for the child's normal functioning, the physician can next fill in details, including family history of headache, medications tried, comorbidities, "stuff" going on at home, triggers, level of stress, and sleep and eating patterns. This information will set the table for the assessment to be shared with the family at the end of the visit, when it is important to reinforce healthy habits for headache prevention. At this point, if worry level has dropped, it is a good time to say something like, "nothing so far makes me worried about a brain tumor."

### Part 3: Physical Examination

With the physical examination, the physician should look particularly for arrest of growth, puberty, or menstruation. Examination of the skin should be thorough, looking for lesions suggestive of a neurocutaneous disorder such as neurofibromatosis. The neurologic examination should include looking for abnormalities of the optic discs, impaired extraocular movements, visual field defects, evidence of ataxia on gait and rapid nose-to-finger movement, and asymmetric reflexes. When the history has already established a pattern of headaches that does not raise concern about serious underlying illness, the physical examination offers the opportunity for the physician to reinforce how reassuring are the benign findings: "With something serious, like a brain tumor, we would expect this part of the examination to be abnormal." If all is normal, a summary statement is appropriate to reassure that nothing in the history or physical examination raises concern about a tumor or anything else serious.

### Part 4: Imaging

Children and adolescents with a history consistent with migraine, who have a normal neurologic examination,

do not need magnetic resonance imaging (MRI). Patients with either systemic symptoms (arrested growth, puberty, or menstruation), abnormal neurologic features on history or physical examination, abrupt onset of severe headache, or a change in pattern to a more chronic headache, should have an MRI.

### Part 5: Management

The following sections will discuss the principles for treatment of migraine and chronic daily headache (see Figure 157-2).

#### Migraine Principles

**PRINCIPLE 1: PATIENTS WITH MIGRAINE HAVE A MORE SENSITIVE BRAIN.** Children with migraine are more sensitive to internal and external triggers than children without headaches. Therefore, migraine sufferers must not miss meals, must sleep at regular intervals, must exercise regularly, and must learn to manage their stress. When alerted, children are adept at figuring out what causes their headaches, often making it possible to modify or eliminate their identified triggers. Some strategies may include having a snack at school, cutting out some extracurricular activities, or assessing for an undiagnosed learning disability.

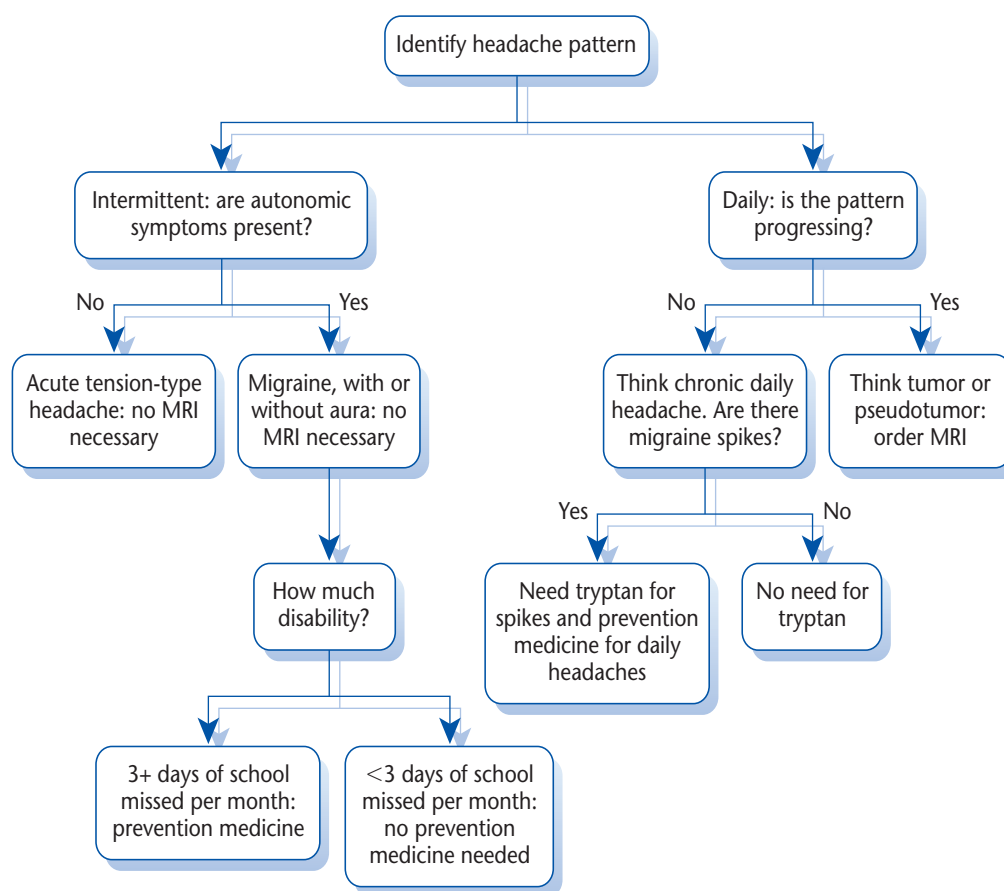

**PRINCIPLE 2: TREAT ATTACKS AT FIRST TWINGE.** With bee sting allergy, one does not wait until anaphylaxis sets in before seeking treatment. Similarly with migraine, medications work best the earlier they are given. Once a migraine is full blown, medication that previously was effective often will not work.

**PRINCIPLE 3: TREAT ATTACKS WITH HIGH DOSES OF ORAL MEDICATION.** A migraine starts a few hours before the patient notices. In particular, the stomach has delayed emptying. Therefore by the time headache is apparent, acute medication should be given in sufficient dose to ensure that a reasonable amount passes through the gastroparetic stomach. For most patients attacks are episodic, so there is no harm if high doses of the medication are used to treat a migraine attack.

**PRINCIPLE 4: DON'T WAIT UNTIL YOU ARE SURE IT IS A MIGRAINE.** Children with migraines who have a tension type headache still respond to triptans; so treating at the first twinge, even if that results in a few headaches being overtreated, offers more benefit than risk. The alternative, waiting too long and compromising the effectiveness of treatment, is far worse.

**PRINCIPLE 5: INVOLVE TEACHER AND NURSE.** Children are in school for a large portion of their lives. If a migraine strikes during the school day, the "alarm bell" should go off for that child, and the teacher and nurse should know to respond with treatment immediately.

**PRINCIPLE 6: TRIPTANS ARE OK.** Once principles 1 to 5 have been addressed, the child with migraines should go home with a plan to include healthy lifestyle changes, urgings to treat early, an explanatory letter to the school with authorization to treat, and a prescription for medication. Only a few triptans (sumatriptan nasal spray and eletriptan tabs) have thus far received FDA approval for use in children. Although studies have demonstrated excellent efficacy, they have not been able to prove benefit over placebo (see Table 157-1 and Table 157-2). Triptans are safe,

**Figure 157-2** Algorithm for pediatric headache.

**Table 157-1** Short-acting Triptans

TRIPTAN	TABLET (mg)	MELT (mg)	NASAL (mg)	SUBCUTANEOUS (mg)
Almotriptan	6.25; 12.5	—	—	—
Eletriptan	20; 40	—	—	—
Rizatriptan	5; 10	5; 10	—	—
Sumatriptan	25; 50; 100	—	5; 20	4; 6
Zolmitriptan	2.5; 5	2.5; 5	5	—

**Table 157-2** Longer Acting and Combination Triptans

TRIPTAN	TABLET (mg)	MELT (mg)	NASAL (mg)	SUBCUTANEOUS (mg)
Frovatriptan	2.5	—	—	—
Naratriptan	1; 2.5	—	—	—
Sumatriptan/Naproxen	85/500	—	—	—

Frovatriptan and naratriptan have longer half-lives than other triptans and may be used for menstrual migraine prophylaxis, or for migraine recurrence.

with no negative outcomes in any of the studies, and are available in low doses for preschool and school-aged children, and for adolescents.

**PRINCIPLE 7: WHO NEEDS PROPHYLAXIS?** A follow-up visit should be scheduled within 2 to 6 weeks to evaluate whether or not progress has been made. At

the follow up, if absenteeism and presenteeism have not diminished to an acceptable level despite the initial interventions described above, the child should receive either a nonpharmacologic or pharmacologic long-term treatment plan. Since they require substantial practice and a large time commitment, nonpharmacologic

**BOX 157-1 Dose Ranges of Preventive Medications**

- Amitriptyline 10–75 mg qhs
- Cyproheptadine 2–18 mg qd
- Divalproex sodium 125–500 mg tid
- Gabapentin 300–1,200 mg tid
- Propranolol 40–120 mg tid
- Topiramate 25–200 mg bid
- Verapamil 80–240 mg tid

*bid*, twice daily; *qd*, every day; *qhs*, every night at bedtime; *tid*, 3 times per day.

treatments work well only for patients invested in their recovery. Relaxation techniques, biofeedback, cognitive behavior therapy, and acupuncture can all be effective. The appropriate strategy is to try to treat comorbidities while avoiding medications that will make other conditions worse. Obese patients should use topiramate and avoid valproate, amitriptyline, and cyproheptadine. A patient with an eating disorder should avoid topiramate. A child with a sleep disorder may benefit from amitriptyline, while for patients with seizures either topiramate, gabapentin, or valproate may be appropriate. With hypertension, either propranolol or verapamil might be effective. Propranolol should not be prescribed for a child with depression. Whichever medication is selected, begin slowly and gradually increase the dose until either therapeutic effect is reached or side effects ensue (see Box 157-1). In the absence of side effects, the medication should be given time to become effective before deciding to change.

**PRINCIPLE 8: WHEN TO REFER.** A primary care physician should be able to prescribe medication, and recommend lifestyle changes and a prevention modality. If improvement is not reported, then referral to a headache specialist is indicated.

### Chronic Daily Headache Principles

#### PRINCIPLE 1: RULE OUT INTRACRANIAL PATHOLOGY.

Unlike migraine, which does not require neuroimaging, chronic daily headache does. Because migraine is so common, with an estimated yearly prevalence of 10% to 25% (at least among adults), many people diagnosed with brain tumors will have also had migraines. The change in the pattern of the headaches to daily chronic is what necessitates the MRI. Computed tomography scanning is not adequate because it does not delineate the posterior fossa well enough.

**PRINCIPLE 2: IDENTIFY PATTERN: TRANSFORMED MIGRAINE VS CHRONIC TENSION TYPE HEADACHE VS NEW DAILY PERSISTENT HEADACHE.** Transformed or chronic migraine will still have migraine spikes with autonomic symptoms, and these will respond to triptans. Sufferers of CTTH do not have migraine, and will not respond to triptans. Patients with NDPH may or may not have migraine spikes: if present, use triptans; if not, then no.

**PRINCIPLE 3: REMOVE ACUTE MEDICATIONS OVERUSED ON A DAILY BASIS.** Overuse of analgesics

can itself lead to headaches. Stopping an overused medication can be done “cold turkey” or gradually over a month or so. If an analgesic is removed acutely, the physician should provide comfort measures, knowing that the headache will get worse for a few days. Such comfort measures might include intranasal dihydroergotamine, or a long-acting drug like frovatriptan or naratriptan. Families should be told to begin the transition over a weekend, preferably a long one, to avoid unnecessary absence from school. If the medication is tapered gently over a month, the patient and family must be warned there will be spikes in headache activity during the withdrawal.

**PRINCIPLE 4: START OR REINFORCE HEALTHY HEADACHE HABITS.**

**PRINCIPLE 5: STAY IN SCHOOL.** Try to avoid health related home schooling, which will only make it harder to reintegrate once the child is better. School attendance forces the child to get up early and have a daily routine. Sleep patterns are easier to regulate, and tendencies towards isolation and depression are lowered.

**PRINCIPLE 6: START A NONPHARMACOLOGIC AND/ORPHARMACOLOGICINTERVENTION.** Someone with daily headache needs an intensive approach, as described in migraine Principle 7.

**PRINCIPLE 7: WATCH OUT FOR UNDETECTED DEPRESSION OR ANXIETY.** Consider referral for counseling as part of the comprehensive approach to the child with chronic headache.

**PRINCIPLE 8: WHEN TO REFER.** Ideally, all children and adolescents with chronic daily headache should be seen by a specialist. Many communities do not have an expert in pediatric headache, or even a pediatric neurologist with an interest in chronic headache. In such a setting, the principles listed above can guide the initiation of treatment, with a timely follow up in a month or so to confirm that progress has been made. If not, then referral is necessary. The primary care physician should also be familiar with local community mental health resources, as well as acupuncturists, physical therapists, and therapists with expertise in biofeedback and relaxation training.

### PROGNOSIS

Short-term studies show great improvement for both episodic and chronic headache with appropriate treatment. However there are no long-term studies tracking either childhood migraine or chronic daily headache cohorts over a long period of time. The goal of the pediatrician should be to prevent chronic headaches by treating migraine early and effectively.

### SUMMARY

This approach allows the physician to diagnose, assess, and treat headache effectively while addressing the concerns of the child and family. Identifying benign patterns of headache reassures the family and the physician, whereas identifying a worrisome pattern directs the child with a potentially serious condition to a diagnostic MRI. Promoting healthy headache activities, identifying comorbidities, and assessing the degree of disability will guide the prescription of acute or chronic medications and nonpharmacologic interventions. The pediatrician can properly manage most

patients with headache, but referral to a specialist is indicated when improvement is not seen after these measures have been implemented.

## Chapter 158 HEARING LOSS

Anne Marie Tharpe, PhD; Douglas P. Sladen, PhD, CCC-A;  
Ann Rothpletz, PhD, CCC-A

Pediatricians are usually the first health care practitioners approached by parents when they have concerns about their child's hearing, and in the course of a typical practice a pediatrician will encounter approximately a dozen children with severe-to-profound hearing loss. Although when the hearing loss is severe parents become concerned about their child's hearing rather early (at approximately 6 months of age), milder degrees of hearing loss typically do not generate concern until the child reaches school age. As such, it is imperative that pediatricians recognize the signs, symptoms, and

risk factors for hearing loss in children and become aware of appropriate referral paths. It is also important to note that despite the widespread implementation of newborn hearing screening, such programs are designed to identify moderate and greater degrees of hearing loss, not mild degrees of loss. Therefore, even a child who passed a hearing screening in the newborn period might still have hearing loss that was missed by or acquired after the screening. This chapter addresses permanent hearing loss in children, not transient losses that often accompany otitis media.

### DEMOGRAPHICS

Rubella and meningitis were once leading causes of severe-to-profound hearing loss in children; but the advent of vaccines for these disorders has virtually eliminated hearing loss caused by congenital rubella and dramatically reduced hearing loss resulting from meningitis. Genetic mutations are now the most common cause of congenital hearing loss, accounting for 50% to 60% of all cases. Consequently, severe-to-profound hearing losses are not as common as they once were, and milder degrees of hearing loss are more prevalent.

Although the prevalence of severe bilateral hearing loss in newborns is estimated to be 1 per 1,000, estimates for mild or minimal losses approach 1 per 20 in school-aged children. In the neonatal intensive care unit (NICU), estimates of hearing loss range from 20 to 40 per 1,000. Minimal hearing loss is defined as thresholds greater than 25 dB HL at 2 or more frequencies above 2,000 Hz, pure tone average between 15 and 25 dB HL bilaterally, or unilateral hearing loss of any degree. This increase in reported prevalence from the newborn period to school age is the result, in part, of not including minimal and mild losses as targets of newborn hearing screening, as well as the addition of losses that progress or are acquired later in childhood (eg, meningitis).

Figure 158-1 is the audiogram of a child with normal hearing sensitivity in both ears such that all the speech sounds fall within the range of audibility. Two of the more typical patterns of minimal-to-mild hearing loss are demonstrated in Figure 158-2 and Figure 158-3. Figure 158-2 is the audiogram of a child with normal hearing sensitivity for all frequencies through 1,000 Hz but a high-frequency hearing loss, a pattern typical with ototoxic drug use or perinatal anoxia. Although this child would be expected to develop speech and language in a timely manner, distortions or omissions of the high-frequency consonant sounds of speech are expected. Parents may report that the child has difficulty hearing in the presence of background noise but seems to have little difficulty in quiet settings. The hearing loss depicted in Figure 158-3 is a profound unilateral loss of the left ear that is not typically identified until a child enters school unless the child receives a hearing screening in the newborn period. A child with unilateral hearing loss may reach age-appropriate speech and language milestones but experience difficulty hearing in the presence of background noise. In addition, children with unilateral

**Figure 158-1** An audiogram reflecting normal hearing sensitivity in both ears.

**Figure 158-3** An audiogram reflecting a profound hearing loss of the left ear.

**Figure 158-2** An audiogram reflecting a high-frequency hearing loss bilaterally.

hearing loss typically demonstrate difficulty localizing sound sources.

Although these patterns of hearing loss are termed *mild* or *minimal*, building evidence suggests that their effect is far from benign. School-aged children who have minimal and mild losses have been found to experience greater academic, communicative, social, and emotional difficulty than normally hearing children. In fact, approximately 35% of children with minimal hearing losses fail at least 1 grade in school compared to an overall failure rate of approximately 3%.

## ASSOCIATED SIGNS AND SYMPTOMS

The Joint Committee on Infant Hearing (JCIH) has published a list of risk factors that provides an excellent starting place when attempting to identify hearing loss in children. However, approximately 35% to 50% of children with hearing loss will not have any known risk factors, making a complete history and keen observation accompanied by hearing screening essential if hearing loss is to be identified early. Although most congenital hearing loss is hereditary, a negative family history is common: 80% of inherited hearing loss results from autosomal-recessive transmission, 18% from autosomal-dominant transmission, and approximately 2% from X-linked recessive transmission. Furthermore, even children with dominantly inherited hearing loss may have families who demonstrate incomplete penetrance. Evidence of the gene expression can be highly variable. In addition, most children with inherited hearing loss are nonsyndromic, providing no additional clues and potentially limiting the pediatrician's level of suspicion. However, 20% of children with congenital sensory hearing loss have an associated syndrome (eg, Alport syndrome, Waardenburg syndrome) or progressive loss (eg, Usher syndrome). Children with Down syndrome are at high risk for conductive hearing loss, as well as a higher-than-average risk for sensory loss.

Infants in the NICU may also be at increased risk for neural conduction or auditory brainstem dysfunction, including auditory neuropathy/dyssynchrony, a disorder characterized by a unique constellation of behavioral and physiologic auditory test results. Children with auditory neuropathy/dyssynchrony have normal outer cochlear hair cell function, but dyssynchronous signal firing at the level of the VIIIth cranial nerve. They exhibit a range of sensitivity from normal hearing to profound hearing loss and poor speech perception ability (often worse than would be expected based

on the degree of hearing loss). Infants who receive intensive neonatal care are at increased risk for auditory neuropathy/dyssynchrony, as are children with a family history of childhood hearing loss and infants with hyperbilirubinemia. However, some children with auditory neuropathy/dyssynchrony have no history of these risk factors. Currently, neither the prevalence of auditory neuropathy/dyssynchrony in newborns nor the natural history of the disorder is clearly understood, and treatment options are not well defined. Many children with auditory neuropathy/dyssynchrony do not benefit from the use of hearing aids but do benefit from cochlear implantation. Audiologic and medical monitoring of infants at risk for auditory neuropathy/dyssynchrony is recommended.

The significant speech and language delays associated with severe to profound childhood hearing loss are typically obvious to parents and physicians; but because identification of milder degrees of hearing loss may prove more elusive, children who exhibit behavioral, social, or academic difficulties should be screened for hearing loss in addition to those with speech and language delays or disorders. Some of the concerns expressed commonly by parents of children with milder forms of hearing loss are included in Table 158-1.

### IDENTIFICATION APPROACHES

The 2007 position statement of the JCIH recommended that identification of and intervention for congenital hearing loss in children should follow a 1-3-6 rule. That is, all infants should have access to hearing screening no later than 1 month of age, confirmation of hearing loss by 3 months of age, and early intervention services no later than 6 months of age. The recommendations of the JCIH are widely accepted, although significant concerns remain with follow-up. A significant percentage of infants who fail the screening do not return for follow-up testing.

According to the Centers for Disease Control and Prevention, only 70% of infants with hearing loss receive appropriate diagnostic testing by 3 months of age and only 56% receive intervention prior to 6 months of age. The pediatrician plays an important role in the identification of childhood hearing loss for several reasons. First, many infants lost to follow up can be recaptured when they are seen in pediatricians' offices for well- or sick-baby visits. Second, even if infants have passed a hearing screening at birth, many children with hearing loss acquire their deficits after the newborn period. Finally, the JCIH recommends that universal newborn hearing screening programs target permanent, bilateral, or unilateral hearing loss averaging 40 dB or greater, a target level that will necessarily miss some minimal and mild hearing loss. The obvious implication is that, even for children who have passed their newborn hearing screenings, pediatricians should be vigilant in monitoring hearing status and, with any suspicion of hearing loss by parents or others, should arrange for hearing assessments by audiologists experienced in working with children.

When an infant or child fails a hearing, speech, or language screening measure in the pediatrician's office, referral for a full audiologic evaluation is recommended. Unfortunately, at least 1 study suggested that more than half of children who failed hearing screenings in primary care practices did not receive rescreenings or referrals for further testing. Audiologists with pediatric experience can define the degree of hearing loss and distinguish among conductive, sensory, and neural types of loss in children of all chronologic ages and developmental levels. Evaluation of hearing in infants and young children consists of a combination of physiologic and behavioral measures. For infants younger than approximately 6 months, testing is typically limited to physiologic measures because their behavioral

**Table 158-1** Explanations for Parental Concerns Regarding Their Child's Hearing Acuity

PARENTAL COMMENTS	EXPLANATIONS
"He can hear me when he wants to hear me. Sometimes he just ignores me."	Children who have mild hearing losses may have little or no difficulty listening in quiet settings. However, if background noise is present they may have more difficulty.
"When I call her, she has to look around for me. She never seems to know where I am in the house."	Children who have unilateral hearing loss often have difficulty localizing a sound source.
"When we are in crowds, I have to call his name several times before he responds."	Children who have high-frequency or other mild hearing losses often have difficulty hearing in the presence of background noise.
"My child is exhausted when she comes home from school."	Children who have minimal or mild hearing loss may be fatigued by the effort exerted to listen throughout the day.
"His speech is very difficult to understand. I don't think it's his hearing, because he always responds when I call him."	Children who have high-frequency hearing loss may have poor speech production because they are unable to hear high-frequency speech sounds (consonants) even though they can hear low- and mid-frequency sounds clearly.
"My child is doing poorly in school, but I know she understands the material because we go over her homework at night."	Children who have minimal hearing loss may have difficulty hearing in school settings because of the background noise. When working at home in a 1-on-1 situation, they may demonstrate no hearing difficulties because the acoustic conditions are good.

responses are not yet reliable enough for defining the extent of hearing loss.

## MANAGEMENT

The early identification of hearing loss in children is of little value if timely intervention does not follow. Many children have conductive and sensorineural hearing losses that are not amenable to medical treatment. For these children, several options remain, the most familiar being traditional hearing aids, which are devices designed to pick up sounds in the child's environment and convert them to electrical signals that are amplified, filtered, and converted back to acoustic signals by a receiver. For children in noisy settings (eg, child care centers, classrooms), frequency-modulated (FM) systems can be used alone or in combination with hearing aids. These systems use a microphone worn by the teacher to amplify only the teacher's voice while minimizing the interfering background noise. The signal is transmitted to the child via an FM signal, which is received by a hearing aid or loudspeaker.

Most children who have hearing loss benefit from some form of amplification. However, in cases of severe-to-profound hearing loss, conventional amplification might not be enough. An alternative to traditional hearing aids for these children is the cochlear implant, a surgically implanted device with electrodes that are coiled into the cochlea to stimulate the auditory nerve with electrical current. Although cochlear implants do not restore normal hearing and children vary markedly in the benefits they derive from the implant, most experience at least an awareness of sound, and some reach a high level of speech recognition, enabling the development of normal speech and language skills. Children are eligible for cochlear implants at age 1 year, although some exceptions for earlier implantation can be made. Children who receive their cochlear implants at an early age (ie, prior to 3 years of age) tend to benefit more from the implant than children who receive their implants at older ages. All children who have cochlear implants are considered at risk for pneumococcal meningitis. Pediatricians should ensure these children are up to date on the pneumococcal vaccine recommendations. All vaccines should be administered at least 2 weeks or more prior to cochlear implant surgery.

As the gatekeepers for children's health care, pediatricians are responsible for recognizing the signs and symptoms of hearing loss in their young patients. Only through the vigilance of pediatricians and other health care practitioners will the age of identification of hearing loss in children be lowered, thus avoiding delays in intervention.

For infants with permanent hearing loss, communication with the state's coordinator for early hearing detection and intervention should ensure that the child and family are enrolled in appropriate early intervention services as soon as possible following identification of hearing loss. Such services can include speech-language and communication intervention, behavioral therapy, and family counseling or support. The pediatrician should also ensure that the child has received a thorough medical evaluation to determine the cause of the hearing loss, including a genetics consultation. Furthermore, because

of the high incidence of vision problems in children with hearing loss, a referral for ophthalmologic evaluation may be warranted. Children with permanent hearing loss are especially vulnerable to the effects of otitis media with effusion because additional hearing loss secondary to the effusion can negatively affect the audibility of speech through hearing aids. Accordingly, pediatricians must closely monitor and manage children who have persistent otitis media with effusion. Finally, approximately 30% to 40% of children with hearing loss have additional disabilities. Therefore periodic developmental screening and surveillance, as recommended by the JCIH, is an integral part of the management of these children.

## WHEN TO REFER

The 2007 position statement of the JCIH lists risk indicators for delayed-onset hearing loss. In addition to any babies who do not pass their newborn hearing screenings, children whose medical history includes 1 or more of the following indicators should be referred for audiologic testing:

- Caregiver concerns regarding hearing, speech, language, or developmental delay
- Family history of permanent childhood hearing loss
- Neonatal intensive care of more than 5 days or any of the following regardless of length of stay: ECMO, assisted ventilation, exposure to ototoxic medications (gentimycin and tobramycin) or loop diuretics (furosemide), hyperbilirubinemia that requires exchange transfusion
- In utero infections, such as CMV, herpes, rubella, syphilis, and toxoplasmosis
- Craniofacial anomalies, including those that involve the pinna, ear canal, ear tags, ear pits, and temporal bone anomalies
- Physical findings such as white forelock that are associated with a syndrome known to include a sensorineural or permanent conductive hearing loss
- Syndromes associated with hearing loss or progressive or late-onset hearing loss such as neurofibromatosis, osteopetrosis, and Usher syndrome; other frequently identified syndromes include Waardenburg, Alport, Pendred, and Jervell and Lange-Nielson
- Neurodegenerative disorders such as Hunter syndrome, or sensory motor neuropathies such as Friedreich ataxia and Charcot-Marie-Tooth syndrome
- Culture-positive postnatal infections associated with sensorineural hearing loss, including confirmed bacterial and viral meningitis
- Head trauma, especially basal skull/temporal bone fractures that require hospitalization
- Chemotherapy

## Chapter 159 HEART MURMURS

Christine Tracy, MD; Christine A. Walsh, MD

A heart murmur is a common finding during the physical examination of children. However, few children with heart murmurs have structural cardiac disease. The challenge for the pediatrician lies in distinguishing innocent murmurs from those that indicate a cardiac abnormality.

### CARDIAC CYCLE AND ASSOCIATED HEART SOUNDS

The pediatrician needs to understand the events of the cardiac cycle and its associated heart sounds when determining the significance of a heart murmur. Heart

**Figure 159-1** Pressure time relationships of the left-sided heart chambers are illustrated during the normal cardiac cycle. AV, aortic valve; ECG, electrocardiogram; LA, left atrium; LV, left ventricle; mm Hg, millimeters of mercury; MV, mitral valve; S<sub>1</sub>, first heart sound; S<sub>2</sub>, second heart sound. (From Lilly LS. *Pathophysiology of Heart Disease*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003. Used by permission.)

sounds are directly related to the hemodynamic events of systole and diastole (Figure 159-1).

The first heart sound (S<sub>1</sub>) is related to the closure of the mitral and tricuspid valves at the end of diastole, when the ventricles are completely filled. The ventricles then undergo a period of isovolumic contraction, followed by opening of the aortic and pulmonary valves. Rapid systolic ejection ensues, followed by a phase of reduced ejection later in systole.

The second heart sound (S<sub>2</sub>) is created by the closure of the aortic and pulmonary valves at the end of systole. The first component of S<sub>2</sub> is created by the closure of the aortic valve (A<sub>2</sub>), and the second component of S<sub>2</sub> is created by the closure of the pulmonary valve (P<sub>2</sub>). During inspiration, P<sub>2</sub> occurs after A<sub>2</sub>, generating an audibly split S<sub>2</sub> (A<sub>2</sub>-P<sub>2</sub>). During exhalation, the closures of the aortic and pulmonary valves are nearly coincident, creating a single S<sub>2</sub>. Abnormal splitting of S<sub>2</sub> can be a clue to structural heart disease, but splitting of S<sub>2</sub> can be difficult to appreciate in infants or children with accelerated heart rates.

Wide splitting of S<sub>2</sub> is associated with prolonged ejection from the right ventricle, as occurs with conditions such as an atrial septal defect (ASD), in which S<sub>2</sub>

is widely split and fixed. A narrowly split  $S_2$  is associated with pulmonary hypertension, in which closure of the pulmonary valve is early, or aortic stenosis, when closure of the aortic valve is delayed. Failure of  $S_2$  to split at all can be the result of simultaneous closure of the aortic and pulmonary valves during all phases of the respiratory cycle, found with conditions that result in high pulmonary artery pressure. A single  $S_2$  can also be associated with certain congenital cardiac anomalies, such as truncus arteriosus and tetralogy of Fallot, or with a single ventricle after the bidirectional Glenn shunt or the Fontan operation.

Third and fourth heart sounds may also be appreciated during physical examination. The third heart sound ( $S_3$ ) is heard early in diastole, during the initial phase of passive rapid ventricular filling. It is a low-frequency sound that can be best heard at the left lower sternal border or at the apex. An apical  $S_3$  can frequently be heard in healthy children, particularly in competitive athletes. Usually pathologic, the fourth heart sound ( $S_4$ ) is also a low-frequency sound but is heard late in diastole, just before  $S_1$ . It results from rapid filling of the ventricle caused by atrial contraction. An  $S_4$  gallop is associated with decreased ventricular compliance (as is seen in cardiomyopathy) and congestive heart failure. Auscultation of an  $S_4$  gallop warrants an evaluation by a pediatric cardiologist.

Clicks may also be audible during the cardiac cycle. Ejection clicks are heard in systole; the timing of the click in the cardiac cycle helps elucidate the cause. An early systolic click, heard just after  $S_1$ , is associated with semilunar valve stenosis (aortic stenosis or pulmonary stenosis) or dilation of the great arteries (the aorta or pulmonary artery). Aortic valve clicks, best heard at the apex or right upper sternal border, do not vary in intensity with respiration. Pulmonary valve clicks increase in intensity with exhalation, and they are best heard along the left sternal border. A midsystolic apical click is heard with mitral valve prolapse and may be accompanied by a late systolic murmur.

## CARDIAC ANATOMY

In evaluating a child with a heart murmur, the physician must understand the anatomy of the heart and its position in the chest. The location of the heart murmur on the chest wall can serve as an important tool in deciding whether the murmur is innocent or pathologic. Figure 159-2 demonstrates the location of the valves of the heart in relation to their position on the chest wall.

## PATIENT EVALUATION

### History

A complete and accurate history is one of the most important aspects of evaluating a cardiac murmur in children because the clinical context in which the murmur occurs provides clues to the cause of a heart murmur. The history should include the patient's chief complaints and medical history, including the birth history and family history (Box 159-1).

### Physical Examination

Evaluation of a cardiac murmur involves much more than auscultation of the heart. A complete physical

**Figure 159-2** Areas of cardiac auscultation are governed by the location of the heart valves in relation to their position on the chest wall. (From Lilly LS. *Pathophysiology of Heart Disease*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003. Used by permission.)

examination in the child or adolescent with a heart murmur is needed to put the murmur in perspective. Pertinent aspects of the physical examination in a patient with a heart murmur are outlined in Table 159-1.

## CARDIAC EVALUATION

A detailed cardiac examination includes thorough inspection, palpation, and auscultation.

### Inspection

Inspection begins with a general assessment of appearance, nutritional status, genetic abnormalities, color, and comfort. The chest wall should then be inspected for abnormalities, including deformities such as a pectus excavatum, asymmetry, and surgical scars.

### Palpation

Palpation should include more than the chest, beginning with the extremities to assess perfusion, pulses, capillary refill, and temperature. The precordium is then palpated to identify the point of maximal impulse (PMI) and to detect thrills. Under normal conditions, the PMI represents the activity of the left ventricle and is palpated in the left fourth or fifth intercostal space in the midclavicular line. Activity of the right ventricle is appreciated in the fourth to fifth intercostal space along the left lower sternal border. Abnormal intensity or location of the PMI or of the right ventricle's activity is suggestive of a cardiac anomaly. Thrills can be palpated in the suprasternal notch (suggesting aortic valve disease or coarctation of the aorta), along the left upper sternal border (suggesting pulmonary valve disease), along the right upper sternal border (suggesting aortic valve disease), or along the left lower sternal border (in association with ventricular septal defects [VSDs]). A thrill is an abnormal finding and warrants referral to a pediatric cardiologist.

**BOX 159-1 Raised Index of Suspicion for Cardiac Disease****PATIENT HISTORY**

- Poor weight gain or difficulty feeding
- Frequent respiratory difficulties or respiratory distress
- Cyanosis
- Exercise intolerance
- Chest pain with exercise
- Unexplained syncope (especially syncope resulting in injury)
- Concurrent syndromic disorder or genetic disease
- Concurrent metabolic disorder or storage disease
- Sickle cell anemia or blood dyscrasias resulting in anemia
- History of cardiotoxic chemotherapy
- Concurrent human immunodeficiency virus disease
- Hypertension

**BIRTH HISTORY**

- Maternal diabetes
- Maternal TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex) infections during pregnancy

- Multiple gestation pregnancy
- In vitro fertilization pregnancy
- Maternal drug use (either legal or illicit), known teratogens
- Abnormal amniocentesis
- Abnormal fetal ultrasound
- Maternal history of congenital heart disease

**FAMILY HISTORY**

- Congenital heart disease
- Sudden cardiac death or unexplained death in young people
- Hypertrophic cardiomyopathy
- Infantile Marfan syndrome

**Table 159-1 Physical Examination to Evaluate a Heart Murmur**

SITE	FINDING
Vital signs	Temperature, heart rate, respiratory rate, height, weight Blood pressures in the right arm, left arm, leg Pulse oximetry on room air (right hand and either foot if infant)
General	Cyanosis, pallor, dysmorphic features, overall distress Breathing pattern: retractions, grunting, nasal flaring
Head and neck	Jugular venous distention Thyromegaly, thyroid nodules
Chest	Chest wall deformity, asymmetry, surgical scars Lung aeration Rales, rhonchi, wheezes, stridor
Cardiac	Inspection Palpation Auscultation
Abdominal	Liver span Tenderness Distention, ascites
Extremities	Perfusion: capillary refill, temperature, quality of pulses Clubbing, cyanosis, edema Arachnodactyly, joint laxity (Marfan syndrome) Increased arm span, upper-to-lower body ratio (Marfan syndrome)

**Auscultation**

A systematic approach to auscultation of the heart ensures that each major anatomic area of the heart is heard in systole and diastole. The major areas of auscultation on the precordium are the apex, the left lower sternal border, the left mid or upper sternal border, and the right upper sternal border. These areas correspond to each atrioventricular and semilunar valve, as well as the outflow tracts of the right and left ventricles (see Figure 159-2). The physician should also auscultate the left and right infraclavicular areas, the axillae, and the back. Auscultation for systolic or continuous blood flow noises (bruits) should be performed over the liver and fontanelle. A bruit suggests an arteriovenous malformation. The patient should be examined in the supine, sitting, and left lateral decubitus positions. Other postural maneuvers, such as squatting or standing, or performing a Valsalva maneuver, may be useful during auscultation. Auscultation includes an assessment of  $S_1$  and  $S_2$ , including the nature of the splitting of  $S_2$ . Noting any  $S_3$  and  $S_4$ , murmurs, clicks, and rubs completes the auscultation.

**EVALUATION OF HEART MURMUR**

A heart murmur is usually the result of turbulent blood flow. Random fluctuations in velocity and pressure during blood flow result in vibration of the surrounding tissue, which is auscultated as a murmur. A complete description of a heart murmur includes its intensity, timing, location, radiation, and quality.

**Intensity**

Murmur intensity is graded on a scale of I to VI for murmurs in systole (Table 159-2). Some cardiologists use a scale of I to IV for murmurs in diastole (Table 159-3). The

Table 159-2 Intensity of Systolic Murmurs	
GRADE	DESCRIPTION
I	Barely audible
II	Soft, but easily audible
III	Moderately loud without a thrill
IV	Moderately loud with a thrill
V	Loud with a thrill, heard with stethoscope partly on the chest
VI	Loud with a thrill, heard with stethoscope off the chest

Table 159-3 Intensity of Diastolic Murmurs	
GRADE	DESCRIPTION
I	Barely audible
II	Soft, but immediately heard
III	Easily heard
IV	Very loud

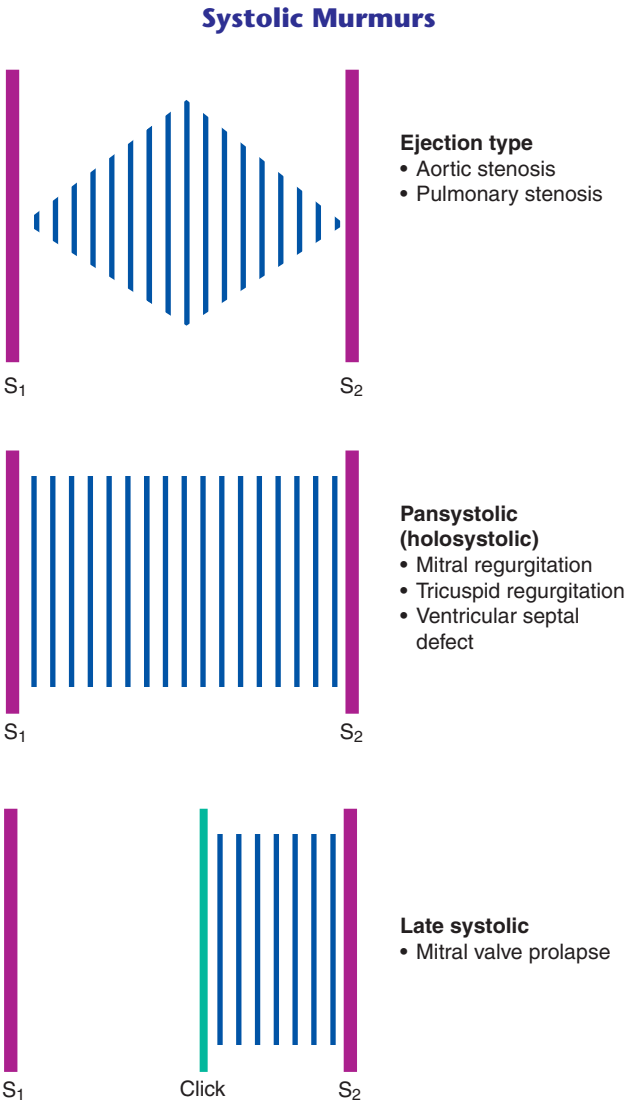

intensity of a murmur does not necessarily reflect the severity of the abnormality. For example, a small VSD may have a very loud murmur, but critical aortic stenosis may have a very soft murmur if cardiac output is low.

Timing

Timing refers to the point in the cardiac cycle at which the murmur is heard. Murmurs are described as being systolic, diastolic, or continuous.

Systolic murmurs occur between atrioventricular valve closure (S<sub>1</sub>) and semilunar valve closure (S<sub>2</sub>). Systolic murmurs are further divided into ejection (crescendo-decrescendo) murmurs, holosystolic (pansystolic) murmurs, and late systolic murmurs (Figure 159-3).

Ejection murmurs, which may be innocent or pathologic, begin shortly after S<sub>1</sub>, peak in intensity, and then end at or before S<sub>2</sub>. All innocent systolic ejection murmurs are grade I to III. Pathologic ejection murmurs can be of any intensity. They may result from obstructed blood flow across a semilunar valve (aortic or pulmonary stenosis), in which case an ejection click may usher in the murmur. Other pathologic ejection murmurs without associated clicks arise from excessive volume crossing a normal semilunar valve (ASD). Holosystolic murmurs start with S<sub>1</sub> and continue to S<sub>2</sub> at the same level of intensity, sometimes obscuring S<sub>2</sub>. These murmurs result from movement of blood from a higher-pressure chamber to a lower-pressure chamber, such as with a VSD or mitral regurgitation. Late systolic murmurs are associated with mitral valve prolapse and resultant mitral regurgitation; they are classically preceded by a mid- or late-systolic click.

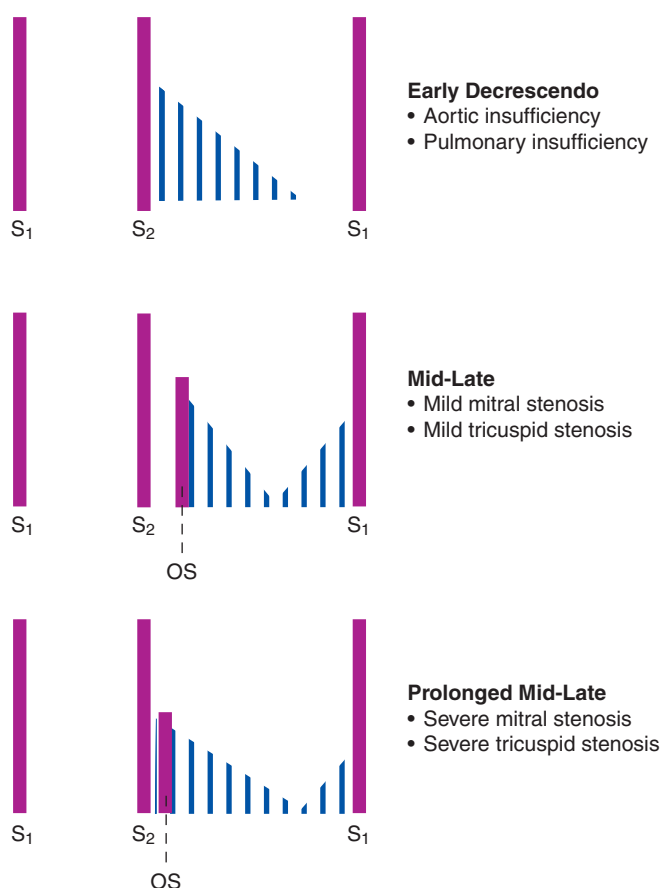

**Figure 159-3** Classification of systolic murmurs. S<sub>1</sub>, first heart sound; S<sub>2</sub>, second heart sound. (From Lilly LS. Pathophysiology of Heart Disease. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003. Used by permission.)

Diastolic murmurs occur between semilunar valve closure (S<sub>2</sub>) and atrioventricular valve closure (S<sub>1</sub>); they are further divided into early-, mid-, and late-diastolic murmurs (Figure 159-4). Diastolic murmurs are all pathologic and require referral to a pediatric cardiologist. Early-diastolic murmurs begin immediately after S<sub>2</sub> and are decrescendo in nature; they become less audible as the ventricle fills. Aortic insufficiency and pulmonary insufficiency are heard in early diastole. Mid-diastolic murmurs occur during rapid ventricular filling. Murmurs of mild mitral and tricuspid stenosis are heard in mid diastole. Late-diastolic (presystolic) murmurs occur near the end of diastole, during atrial contraction. Severe mitral stenosis or tricuspid stenosis murmurs increase in late diastole.

Continuous murmurs extend across portions of systole and diastole. They are almost always vascular in

### Diastolic Murmurs

**Figure 159-4** Classification of diastolic murmurs. OS, opening snap; S1, first heart sound; S2, second heart sound. (From Lilly LS. *Pathophysiology of Heart Disease*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003. Used by permission.)

origin and are caused by aortopulmonary (eg, patent ductus arteriosus) or arteriovenous (eg, arteriovenous malformation) connections, turbulent flow in collateral arteries (eg, coarctation of the aorta), turbulent flow in veins (eg, venous hum), or a surgical shunt. With the exception of the innocent venous hum (Table 159-4), continuous murmurs are pathologic. They tend to wax and wane in intensity through the cardiac cycle, often diminishing in late diastole (Figure 159-5). A somewhat different auscultatory phenomenon from the continuous murmur, the to-and-fro murmur describes an ejection murmur heard in systole, coupled to a decrescendo murmur early in diastole. Combined aortic stenosis and aortic insufficiency or combined pulmonary stenosis and pulmonary insufficiency produces to-and-fro murmurs.

#### Location and Radiation

Location refers to the area where the murmur is heard the best. Radiation means the murmur is also audible with unexpected intensity at some distance from its location. As seen in Figure 159-2, location helps

narrow the differential diagnosis of the murmur. Radiation of the murmur can also be very helpful diagnostically. For example, murmurs that radiate to the neck tend to be of aortic or left ventricular outflow tract origin, whereas a murmur heard best at the left upper sternal border with radiation to the axillae and back is more likely to be pulmonary in origin.

#### Quality and Behavior With Maneuvers

Quality refers to the pitch and nature of a murmur. Pitch is generally described as either high or low. High-pitched murmurs occur when the pressure differential involved is large. For example, aortic insufficiency is a high-pitched murmur. Low-pitched murmurs occur when a lower pressure differential is involved. Pulmonary insufficiency is a low-pitched murmur. Systolic murmurs are described as harsh, blowing, musical, or vibratory. Diastolic murmurs are described as blowing, rumbling, crescendo, or decrescendo.

Postural maneuvers are useful in distinguishing among different types of murmurs. Innocent murmurs tend to become louder when the patient moves from an upright to a supine position. Placing the patient in the left lateral decubitus position increases the murmur of mitral stenosis. A Valsalva maneuver, by decreasing venous return, makes the murmur of aortic stenosis softer; however, it makes the murmur of hypertrophic obstructive cardiomyopathy louder. Valsalva maneuver also decreases the murmurs associated with a VSD and mitral regurgitation and can nearly eliminate innocent Still murmurs (Table 159-4). Squatting increases venous return and makes the murmur of hypertrophic obstructive cardiomyopathy softer. Standing up after squatting can accentuate the murmur or click of mitral valve prolapse by moving the murmur and click closer to S1. Recumbent positioning and/or turning the head can eliminate the innocent continuous murmur of a venous hum.

### CONCLUSION

Pediatricians commonly evaluate childhood murmurs. Most murmurs in children and adolescents are innocent. They do not reflect cardiac disease, and they do not require referral to a pediatric cardiologist, prophylaxis against endocarditis, or exercise restriction. Innocent murmurs are generally short systolic murmurs and are less than grade IV. They are often low pitched, vibratory, or musical; are best heard in the supine position; and often diminish when the patient is upright or during a Valsalva maneuver. Most innocent murmurs can be recognized with confidence based on the clinical history and careful physical examination. Further evaluation is required for any murmur for which suspicion persists that it may be pathologic.

#### WHEN TO REFER

- Patient, maternal, or family history raising index of suspicion for heart disease
- All diastolic murmurs
- Continuous murmurs, except venous hum
- All systolic murmurs grade IV or higher

MURMUR	INTENSITY	TIMING	LOCATION	QUALITY
Still	I–III/VI	Early–mid systolic	LM–LLSB or apex	Vibratory, musical
Pulmonary	I–III/VI	Early–mid systolic	LUSB	Low pitched, ejection
Venous hum	I–III/VI	Continuous	Right (rarely left) infra- or supraclavicular	Low pitched, disappears with head turn, supine position, jugular compression

**Figure 159-5** Continuous murmur versus to-and-fro murmur. AS/AI, aortic stenosis and aortic insufficiency; PDA, patent ductus arteriosus; PS/PI, pulmonary stenosis and pulmonary insufficiency; S1, first heart sound; S2, second heart sound. (From Lilly LS. *Pathophysiology of Heart Disease*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003. Used by permission.)

- All systolic murmurs not clearly fitting the pattern of innocent murmur
- Auscultation of an S4 gallop
- A thrill is an abnormal finding and warrants referral to a cardiologist
- Cyanosis, clubbing
- Higher blood pressure in one or both arms than a leg
- Congestive heart failure—rales, respiratory distress, hepatomegaly, edema
- Abnormal electrocardiogram
- Symptoms that suggest reactive airway disease that do not improve with appropriate medical therapy

Chapter 160  
HEMATURIA

Kimberly J. Reidy, MD; Marcela Del Rio, MD

Hematuria may manifest as a dramatic change in the color of a child's urine, with the appearance of blood on a diaper or underwear, or as a finding on a urinalysis. Red or brown (cola-colored) urine with red blood cells (RBCs) seen on microscopy is typical of macroscopic (or gross) hematuria. In general, urologic causes of gross hematuria often present with red or pink urine, while glomerular hematuria presents with brown-, tea-, or cola-colored urine. In a retrospective study of children presenting to a pediatric emergency department, gross hematuria had an incidence of 1.3 per 1,000 visits. Microscopic hematuria (defined as >5 RBCs per high power field seen on microscopy of centrifuged urine) is more common. On routine screening urinalysis, studies suggest up to 32 per 1,000 girls and 14 per 1,000 boys will have microscopic hematuria. The American Academy of Pediatrics (AAP) currently does not recommend routine screening urinalyses in asymptomatic children.

The most likely causes of macroscopic and microscopic hematuria differ (Figure 160-1 and Box 160-1). Macroscopic hematuria may originate from any component of the genitourinary tract, and the differential diagnosis, in addition to infection, includes glomerular, interstitial, and tubular diseases and bleeding from trauma, stones, or coagulopathy. Many of the causes of macroscopic hematuria, such as infection, nephrolithiasis, and glomerulonephritis, may also present with microscopic hematuria. Overall, the

**Figure 160-1** Differential diagnosis of macroscopic hematuria in children.

### BOX 160-1 Causes of Microscopic Hematuria

- Transient
- Thin basement membrane disease
- Idiopathic hypercalciuria
- Immunoglobulin A (IgA) nephropathy or Alport syndrome
- Sickle cell anemia or trait
- Trauma or exercise
- Postinfectious glomerulonephritis
- Nephrolithiasis
- Other glomerular disease or glomerulonephritis
  - Focal and segmental glomerulosclerosis
  - Henoch-Schönlein purpura syndrome
  - Systemic lupus erythematosus
  - Membranoproliferative glomerulonephritis
  - Membranous glomerulonephritis
- Congenital abnormality
  - Ureteropelvic junction obstruction
  - Cystic disease
- Pyelonephritis or infection
- Vascular malformation
- Drugs or toxins

most common causes of asymptomatic isolated microscopic hematuria are thin basement membrane disease, idiopathic hypercalciuria, immunoglobulin A (IgA) nephropathy, and sickle cell disease or trait.

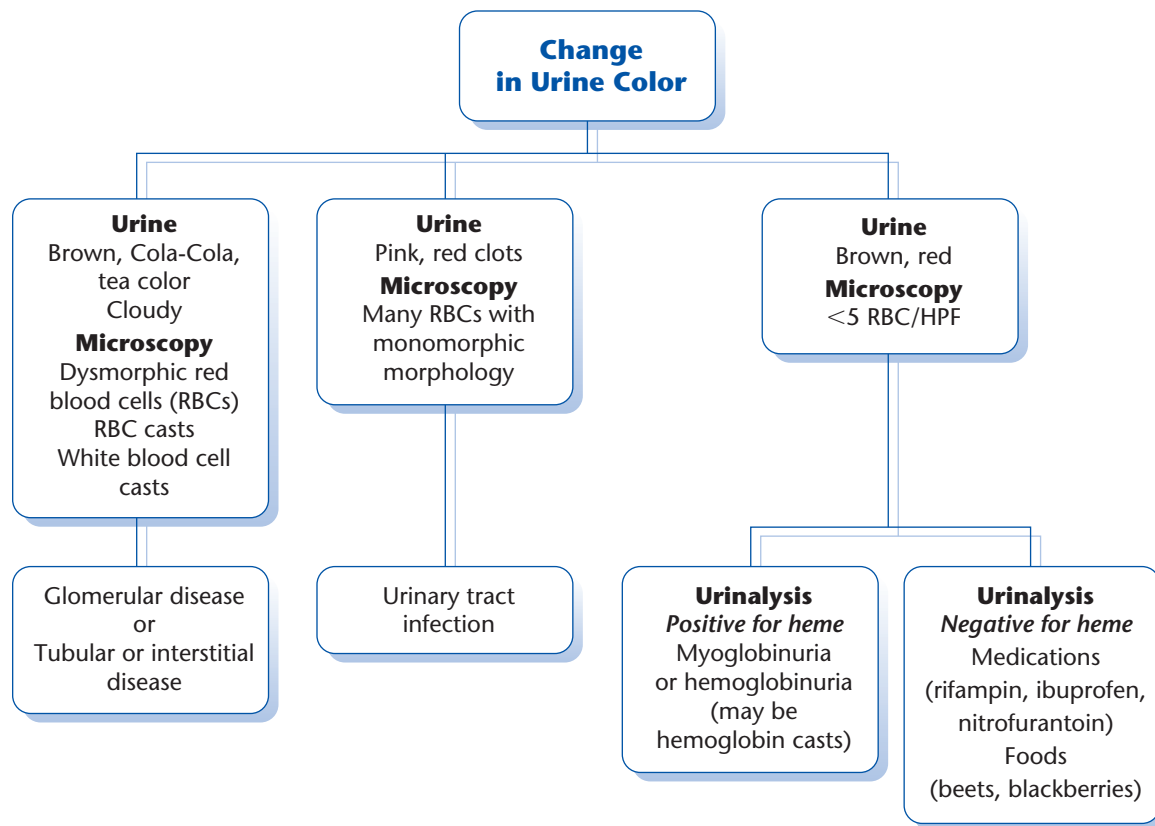

## MACROSCOPIC HEMATURIA

The first and most important step in evaluating macroscopic hematuria is obtaining a detailed description of the urine (Figure 160-2). Renal or glomerular causes of hematuria result in tea- or cola-colored urine, as

opposed to hematuria of lower-tract origin, which causes red or pink urine. In addition to color, highly turbid urine may indicate the presence of cells and suggests glomerular disease or infection. Blood clots suggest urinary tract bleeding. The timing of the bleeding may be helpful (eg, if it occurs only with the onset of micturation, then the source of the bleeding is likely to be in the lower urinary tract).

Associated signs and symptoms from a detailed history and physical examination will dictate laboratory and radiologic evaluation. Important historical elements include associated urinary symptoms, such as dysuria, frequency, urgency, or enuresis. A decrease in urine output should prompt particular concern and rapid evaluation and treatment. A review of systems should include associated symptoms of abdominal pain or colic, upper respiratory infection symptoms, swelling of extremities, or blurry vision or headaches suggestive of hypertension. The history should be explored for prior episodes of hematuria, preceding infections (either documented group A streptococcal throat infection or a history of sore throat or skin infection), history of trauma, or other illnesses, such as the presence of sickle cell trait or disease. Systemic illnesses may be suggested by a history of fever, malaise, weight loss, alopecia, rash, or joint pains, which may be seen in rheumatologic disease. The age of the patient is an important factor to consider—certain causes of hematuria, such as renal vein thrombosis and tumors, are more common in infants. Important points on the family history include other family members with hematuria, kidney or rheumatologic disease, and any history of deafness, which may occur with Alport syndrome.

A thorough physical examination should include measurement of blood pressure, abdominal or costovertebral angle tenderness, a search for evidence of local trauma to the genitourinary tract, inspection and palpation for periorbital, genital, or extremity edema, and examination of the skin for rashes. Hematuria in association with edema and hypertension suggests glomerulonephritis.

**Figure 160-2** Evaluation for macroscopic hematuria begins with the examination of the urine.

**Figure 160-3** Urinary findings in hematuria

Laboratory evaluation begins with a urinalysis with microscopic examination of a fresh-spun urine sample to confirm the presence of red blood cells. Dysmorphic red blood cells and red blood cell casts are pathognomonic of hematuria of glomerular origin (see Figure 160-3). If the urine dipstick is positive for blood and fewer than 5 red blood cells are found on microscopy, then the diagnosis is hemoglobinuria or

myoglobinuria rather than hematuria. Several drugs, including rifampin, ibuprofen, and nitrofurantoin, as well as foods such as beets and blackberries, can discolor urine to give it the appearance of hematuria, but urinalysis will be negative for blood. The presence of calcium, uric acid, or cystine crystals in the urine is suggestive of nephrolithiasis. Identification of white blood cell casts on microscopy or leukocyte esterase or nitrate positivity on urine dipstick point to infectious causes of hematuria.

Further evaluation is determined by the most likely cause of the blood in the urine. For example, a workup for suspected glomerular hematuria might include evaluation of serum electrolytes, blood urea nitrogen, creatinine, calcium, and phosphorus to assess renal function and liver function tests if there is a nephrotic component. Antinuclear antibody test, complement studies (C3, C4, and total complement), streptozyme (deoxyribonuclease B) and streptolysin O antibody titers may help determine the etiology of a glomerulonephritis. Throat culture or rapid testing for group A  $\beta$ -hemolytic streptococci is indicated with a history of sore throat. A urine culture should be performed on all patients with urinary symptoms or on infants, because infection is a common cause of hematuria. Proteinuria on urinalysis should be further evaluated with a first-morning void for protein-to-creatinine ratio. In patients with suspected nonglomerular macroscopic hematuria, a renal-bladder sonogram is indicated to evaluate for cystic disease, congenital obstruction,

tumors (including Wilms tumor), nephrolithiasis, or parenchymal renal disease. A renal doppler study is needed to evaluate for suspected vascular thrombosis, renal infarcts, or renal artery stenosis.

Evaluation of glomerular hematuria may be continued as an outpatient or inpatient. Indications for admission include decreased urine output, hypertension, azotemia, or renal insufficiency. Renal biopsy is absolutely indicated in cases of hematuria with nephrotic syndrome, recurrent hematuria, azotemia, or renal insufficiency. Renal biopsy may be considered if a family history of hematuria exists or if the history or laboratory evaluation is suggestive of rheumatologic disease, such as systemic lupus erythematosus.

Management of glomerular disease will depend on the cause of the glomerulonephritis. The most common glomerulonephritis is postinfectious, an entity characterized by a prodromal infection (often a streptococcal skin or throat infection but also viral infections, such as varicella, cytomegalovirus, Epstein-Barr virus, hepatitis B and C, and parasitic infections such as toxoplasmosis) between 1 and 6 weeks before the onset of hematuria. Other causes of acute postinfectious glomerulonephritis include ventriculoperitoneal shunt infections (shunt nephritis) and acute or subacute endocarditis. Low complement (C3) and elevated streptolysin O antibodies are characteristic of post-streptococcal glomerulonephritis. Post-streptococcal glomerulonephritis is typically self-limited with a good prognosis for long-term renal function. Admission may be required for renal insufficiency, oliguria, or acute hypertension (the latter requiring aggressive management with fluid and salt restriction and antihypertensive medications).

Other types of glomerulonephritis often require management by a nephrologist. The most common chronic glomerulonephritis worldwide is IgA nephropathy, although it is more often diagnosed in adults than children. IgA nephropathy characteristically results in persistent microhematuria with intermittent episodes of gross hematuria associated with upper respiratory infections. Long-term outcome is variable, with 20% to

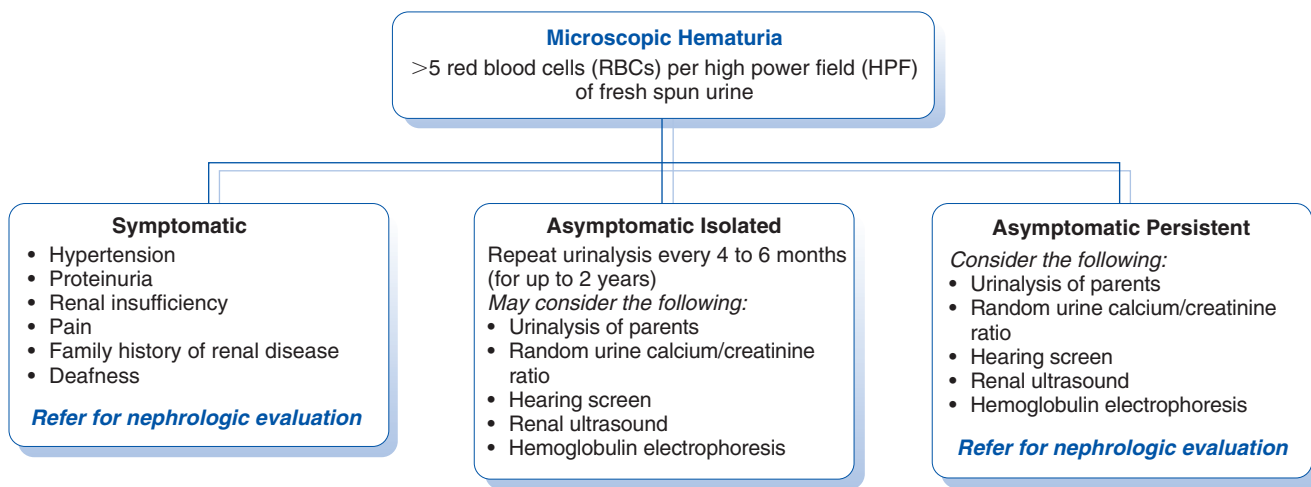

40% of children progressing to end-stage kidney disease. Proteinuria and hypertension are poor prognostic indicators. Henoch-Schönlein purpura (HSP), a common systemic vasculitis in children, is often associated with crampy abdominal pain, arthralgia, and palpable purpura, and can produce glomerulonephritis with hematuria.

Management of nonglomerular hematuria depends on the cause. Further imaging with computed tomography may be indicated. Patients with sickle-cell disease and macroscopic hematuria from papillary necrosis may require admission for intravenous hydration. Trauma, tumors, cystic disease, congenital obstruction, hemorrhagic cystitis, and lower urinary tract bleeding often require urologic evaluation, which may include direct visualization by cystoscopy. Children with nephrolithiasis benefit from both nephrologic and urologic evaluation.

## MICROSCOPIC HEMATURIA

The evaluation of microscopic hematuria involves a thorough history and physical examination. A family history of deafness or kidney disease and the presence of hypertension, proteinuria, or edema should prompt referral to a pediatric nephrologist for further evaluation. In the absence of any other signs and symptoms, microhematuria is often benign and, in many cases, resolves spontaneously (transient hematuria). Therefore, in an asymptomatic, normotensive child with isolated microhematuria, repeating a urinalysis on 1 or more occasions is often prudent before further evaluation. School-aged children may be observed in excess of 2 years before more extensive testing is undertaken. Figure 160-4 shows a proposed algorithm for the evaluation of microscopic hematuria. Significant proteinuria or the occurrence of gross hematuria should prompt referral to a pediatric nephrologist.

Hereditary nephritis includes a spectrum of familial hematuria that ranges from benign thin basement membrane nephropathy (TBMN) to progressive Alport syndrome. TBMN is a common cause of persistent microhematuria. TBMN is characterized by painless

**Figure 160-4** Evaluation of microscopic hematuria.

microscopic hematuria with minimal proteinuria and normal renal function. Renal biopsy reveals uniform thinning of the glomerular basement membrane. TBMN is also called thin basement membrane disease, hereditary hematuria, benign familial hematuria, and benign hereditary nephritis. Because it is transmitted in an autosomal-dominant fashion, a family history of microscopic hematuria without symptomatic renal disease, or an asymptomatic parent testing positive for hematuria, suggests the diagnosis of TBMN. The overall prevalence is estimated at 1% to 10% of the population. It is more common in females than in males and has been diagnosed in children as young as 1 year of age. Between 5% and 22% of affected individuals will have an episode of gross hematuria associated with an infection or exercise. No evidence has been found to support treatment of TBMN, which is typically nonprogressive. However, affected children should be monitored for with a yearly urinalysis and blood pressure check throughout their lives, because they are at higher risk of hypertension, proteinuria, and renal insufficiency in later adulthood.

Another common cause of microscopic hematuria is hypercalciuria, defined as a urine calcium-to-creatinine ratio of greater than 0.21 or more than 4 mg/kg/day of excreted calcium on a 24-hour urine collection. Children with hematuria and underlying hypercalciuria are at risk for nephrolithiasis, with the risk seeming to be greater in older children, in children with gross rather than microscopic hematuria, and when there is a family history of stone formation.

Significant proteinuria or the occurrence of gross hematuria should prompt referral to a pediatric nephrologist.

### BLOOD ON A DIAPER OR UNDERWEAR

Blood on a diaper or underwear most commonly occurs with trauma to or manipulation of the genital area. Localized irritation of the meatus in boys is the most frequent cause and responds to treatment with petroleum jelly and reassurance to the parent without further evaluation. Sexual abuse is on the differential diagnosis. Nonurethral sources of bleeding, such as perineal or vaginal bleeding, should be considered. Again, a urinalysis is useful to confirm that hematuria is the source of the discoloration. “Red diaper syndrome” can result from infection with *Serratia marcescens* (deposits of reddish pigment), or uric acid crystals (reddish/brown or pink crystals) that can be found in the normal or dehydrated newborn.

### CONCLUSION

Key points for the primary care physician include the following:

- Gross hematuria is a common sign of glomerular and urologic disease.
- Hematuria of glomerular origin presents with tea- or cola-colored urine.
- Hematuria arising from the urinary tract is usually red-pink, with or without clots.
- Red blood cell casts are the hallmark of hematuria of glomerular origin.
- Proteinuria is a more important prognostic finding than gross hematuria.

- Every child with gross hematuria should have a renal ultrasound to rule out nephrolithiasis, tumor, or urologic abnormalities, such as cystic disease and obstructive uropathy.
- Gross hematuria rarely is a cause of anemia.
- Most children with isolated microscopic hematuria do not have a serious or treatable cause for the hematuria and do not require an extensive workup.
- Hematuria of glomerular origin is typically painless.

### WHEN TO REFER

- Macroscopic hematuria
- Hematuria associated with pain
- Persistent microscopic hematuria, especially with associated proteinuria, hypertension, hearing loss, or family history of renal disease or deafness

### WHEN TO ADMIT

- When hematuria (with or without proteinuria) is associated with the following:
  - Severe abdominal or flank pain
  - Congestive heart failure or fluid overload indicative of oliguria or anuria
  - Hypertension
  - Renal insufficiency
  - Anasarca (generalized edema)

## Chapter 161

# HEMOPTYSIS

Scott A. Schroeder, MD

*Hemoptysis*, the spitting or coughing of blood that originates within the thorax, can vary from flecks of blood in the sputum to massive, life-threatening bleeding that can lead to respiratory distress or death. Unlike in adults, for whom more than 100 different causes of hemoptysis have been described, hemoptysis is a rare occurrence in children; it is most commonly associated with previously diagnosed congenital heart disease or cystic fibrosis (CF), although other causes include infectious respiratory illnesses and, rarely, neoplasms. Acute hemoptysis, respiratory failure, and cyanosis may be the result of exposure to mold growing in water-damaged homes or to environmental tobacco smoke. Affected children need to be hospitalized and placed on mechanical ventilation.

Four important considerations should be kept in mind when evaluating children who have hemoptysis. First, it is necessary to determine whether the bleeding requires an emergency resuscitative effort. Second, what seems to be hemoptysis may actually be bleeding from the upper airway or gastrointestinal tract; thus, the source of the bleeding should be established. Third, children without chronic diseases who develop hemoptysis with associated symptoms of a lower respiratory tract infection usually have mild, self-limited bleeding that requires no specific treatment other than management of the underlying acute illness. Fourth, the management of hemoptysis that arises from a localized site differs from that which causes a diffuse alveolar hemorrhage, because the latter may be the presenting sign of an underlying immunologic or rheumatologic disorder.

## **PATHOGENESIS**

Hemoptysis can result from the disruption of either arm of the dual pulmonary vascular system or from damage to the alveolar endothelial junction. The low-pressure, high-capacitance pulmonary arterial system accepts the entire cardiac output from the right ventricle and carries blood to be oxygenated at the pulmonary capillaries before returning the oxygenated blood to the left atrium through the pulmonary veins. Although the pulmonary arteries travel alongside the bronchial tree, they interact with the airways only at the level of the terminal bronchioles. The second arm of the blood supply within the lungs is the high-pressure bronchial system. The bronchial arteries originate from the aorta or, less commonly, the intercostal arteries, and they receive only 1% to 2% of the cardiac output. The bronchial arteries enter the lungs at the hilum, and as they branch with the bronchi they anastomose and penetrate the bronchial mucosa, forming an extensive submucosal plexus. The high-flow, low-pressure pulmonary capillary bed allows the exchange of gases between the

alveoli and the capillaries to occur with little risk for hemorrhage in the normal state.

Localized hemoptysis, in most cases, is the result of bleeding from the high-pressure bronchial circulation in inflamed airways. The pulmonary circulation is rarely to blame for hemoptysis except in necrotic infarcts and from pulmonary arterial aneurysms in tubercular cavities. Both of these conditions are extremely rare in children. Inflammation within the lungs, pulmonary vascular obstruction, and neoplasia can all cause an increase in the bronchial circulation. In chronic inflammatory conditions, such as bronchiectasis, the cardiac output to the bronchial circulation can triple, and bronchopulmonary anastomoses are increased, thereby increasing the potential for erosion of vessels in the presence of superimposed infection. The pathogenesis of disease states with diffuse pulmonary hemorrhage—for example, necrotizing granulomatous vasculitis—is not entirely understood, but the bleeding into the alveoli seems to result from neutrophil-mediated injury to pulmonary capillaries with interstitial and air-space fibrosis from the chronic hemorrhage.

## **ETIOLOGY**

### **Hemoptysis in Children Without a Preexisting Medical Condition**

In children who do not have a preexisting medical condition, the most common causes of hemoptysis are acute infections of the tracheobronchial tree, acute infectious pneumonias, and the aspiration of a foreign body. A child with a pneumococcal pneumonia who is old enough to expectorate is classically febrile, seems ill, and has a cough that is productive of rusty sputum. Certain other bacterial and viral lower respiratory tract infections can cause hemoptysis; in these cases, the hemoptysis usually occurs early in the course of the illness, is self-limited, and consists of only blood-tinged sputum. Globally, tuberculosis, echinococcus, and paragonimiasis are probably the most common causes of hemoptysis in children (Table 161-1).

After acute infectious processes, the most common cause of hemoptysis in a previously healthy child is the aspiration of a foreign body. In many children who aspirate foreign bodies, the initial choking episode is not observed or not remembered. A bout of paroxysmal coughing may occur after the initial event, but as the cough receptors in the bronchi or trachea adapt, the coughing will stop. Over time, and depending on the location and composition of the foreign object, subsequent inflammation will occur, which may result in airway obstruction, with wheezing or recurrent pneumonitis. If neovascularization of granulation tissue in the airways occurs, or if bronchiectasis develops, then hemoptysis can occur weeks to months after the initial event. Only 40% of children with a foreign-body aspiration will exhibit the classic triad of wheezing, cough, and decreased breath sounds distal to the site of obstruction. The chest radiograph will be normal in 25% of children with bronchial foreign bodies and in more than 50% of children with tracheal foreign bodies.

Because only 10% of aspirated foreign bodies are radiopaque, a normal chest radiograph does not

**Table 161-1** Common, Less Common, and Uncommon Causes of Hemoptysis

POPULATION	CAUSE	DIAGNOSTIC CLUES
Common causes in children who have no preexisting medical problems	Pneumonia	Usually rusty-colored sputum early in the course of the illness
	Foreign-body aspiration	Needs a high index of suspicion; may have a normal chest radiograph; localized wheezing that does not respond to medical therapy
Less common causes in children who have no preexisting medical problems	Pulmonary tuberculosis	Usually with systemic manifestations, such as anorexia and weight loss; may have negative purified protein derivative test
	Autoimmune disorders	Diffuse pulmonary hemorrhage, often with weight loss or other systems involved, including the kidneys and joints
	Congenital malformations	Symptoms depend on the nature of the lesion; may be associated with massive hemoptysis or respiratory distress in newborns
Rare causes in children who have no preexisting medical problems	Primary pulmonary neoplasms	Primary pulmonary cancers reported in fewer than 500 children; usually present with cough and recurrent pneumonitis
	Pulmonary embolism	Associated with pleuritic pain, cough, and dyspnea; oral contraceptive use; recent abortion; trauma to lower extremities
	Parasitic lung infections	Travel to endemic areas or sheep-raising areas; peripheral eosinophilia
	Arteriovenous malformations	Recurrent epistaxis, a positive family history for hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome), or cutaneous telangiectasia
	Idiopathic pulmonary hemosiderosis	Cough, wheezing, iron-deficiency anemia, and diffuse pulmonary hemorrhage on chest radiograph
Common causes in children who have a preexisting medical problem	Catamenial hemoptysis	Hemoptysis occurs with onset of menses
	Factitious hemoptysis	Form of Münchhausen syndrome
	Bronchiectasis	Blood-tinged sputum, clubbing, signs of increasing airway inflammation
	Congenital heart lesions	Seen with Eisenmenger complex and pulmonary venous congestion
Less common causes in children who have a preexisting medical problem	Sickle cell anemia	Hemoptysis associated with acute chest syndrome or pulmonary infarction
	Aspergillosis	Seen in association with CF or asthma; peripheral eosinophilia and fungi seen on Gram stain of sputum

CF, cystic fibrosis.

preclude aspiration. Inspiratory and expiratory films, decubitus films, and fluoroscopy may be necessary to confirm the diagnosis. If the evidence for aspiration is definitive, then referral for rigid bronchoscopy to a pediatric surgeon or otolaryngologist experienced in retrieving foreign bodies is indicated. If the diagnosis is uncertain, then referral to a pediatric pulmonologist or other physician skilled in the use of the fiberoptic bronchoscopy is appropriate to determine whether a foreign body is present.

### Diffuse Pulmonary Hemorrhage

Children with acute hemoptysis, cough, wheezing, or crackles, diffuse patchy infiltrates on chest radiograph, and bronchoscopic evidence of blood in all lobes or hemosiderin-laden macrophages should be assumed to have diffuse pulmonary hemorrhage or hemosiderosis. The 4 categories of diffuse hemorrhage syndromes that occur in children are those associated with antglomerular basement membrane

antibodies in serum or tissue (eg, Goodpasture syndrome), those associated with an autoimmune-mediated disease (eg, systemic lupus erythematosus), those without any immunologic abnormalities but associated with antibodies to cow's milk, and idiopathic pulmonary hemosiderosis (IPH). All of these conditions are exceedingly rare.

*Goodpasture syndrome*, which occurs most commonly in men in their second and third decades, is characterized by diffuse pulmonary hemorrhage, antglomerular basement membrane antibodies in serum or tissue, and glomerulonephritis. The autoimmune diseases, which are more common in girls and women, rarely produce hemoptysis alone; more commonly, systemic manifestations occur, including fever, weight loss, malaise, anorexia, amenorrhea, rashes, or hypertension, as well as hemoptysis. Treatment for the pulmonary hemorrhage in these disorders should be directed at the underlying disease process.

In *Heiner syndrome*, or pulmonary hemosiderosis associated with cow milk allergy, infants and children exhibit failure to thrive, vomiting, gastrointestinal bleeding, and upper respiratory tract congestion, in addition to hemoptysis. Although the mechanism whereby the milk causes the multisystem damage is unclear, elimination of milk from the diet results in a dramatic improvement in the children.

In IPH, no evidence for an immune-mediated mechanism is found. Most children with IPH are diagnosed before the age of 7 years or after the age of 16 years. They usually have respiratory distress, bilateral alveolar infiltrates, and iron-deficiency anemia. The treatment of the acute exacerbations of IPH includes the use of high-dose oral or intravenous corticosteroids, as well as supportive care for the acute bleeding into the lungs. Controversy exists regarding the need for chronic immunosuppressive therapy, but most physicians caring for children with IPH use azathioprine, chloroquine, or cyclophosphamide to help maintain normal lung function and prevent further episodes of hemoptysis.

### Primary Pulmonary Neoplasms

Unlike in adults, primary pulmonary neoplasms are extremely rare in children, especially immunocompetent children. Fewer than 5% of tumors reported in the literature were associated with hemoptysis. The most common presentations of primary pulmonary neoplasms in children are fever, cough, and pleural pain.

### Hemoptysis in Children With a Preexisting Medical Condition

The most common chronic disease associated with hemoptysis is CF. Hemoptysis in CF, which usually begins in the second or third decade of life, can range from the production of blood-tinged sputum with excessive coughing to massive bleeding. Mild hemoptysis can be treated with conservative medical therapy, which includes bed rest, intravenous or oral antibiotics, withholding of chest physiotherapy, and administration of vitamin K. Massive hemoptysis has an annual incidence of 1% among patients with CF and carries a high mortality rate. Massive or recurrent hemoptysis in CF and other diseases is now treated with bronchial artery embolization. Despite a moderately high rate of recurrent bleeding, embolization can relieve symptoms for a significant period. A team composed of a pulmonologist, thoracic surgeon, and interventional radiologist should evaluate these patients before bronchial artery embolization.

Although the number of children with bronchiectasis has declined because of the decline of tuberculosis and the use of effective vaccines against measles and pertussis, children with immunodeficiencies, recurrent aspiration, and ciliary dyskinesias may develop bronchiectasis and have episodes of hemoptysis. In most cases, a history of a chronic, productive cough with purulent sputum and changes on the lung examination precede the hemoptysis. The diagnosis is made by high-resolution chest tomography, and management is similar to that of CF.

Hemoptysis is a well-recognized complication of congenital heart disease but is becoming an uncommon

problem because of advances in corrective cardiac surgery. Hemoptysis in primary or secondary pulmonary hypertension occurs as a result of thromboembolic events. In right ventricular outflow obstruction with increased bronchial arterial circulation, hemorrhage from enlarged and tortuous bronchial arteries can produce hemoptysis. Pulmonary vascular obstructive disease can lead to hemoptysis because of pulmonary hypertension, as well as to thrombosis. These vascular changes take years to develop and are usually first observed in adolescents.

### EVALUATION

As with any potential emergency, the first question to be answered about hemoptysis is, "Is it life threatening?" Because the expectoration of blood understandably arouses anxiety and fear, and because the blood can be mixed with saliva or phlegm and swallowed or aspirated, accurately determining the amount of blood is often difficult for children and their parents. In adults, the quantity of expectorated blood does not correlate with the seriousness of the underlying disease. In children, the gravity of the hemoptysis is determined more by the child's clinical status and ability to keep the airway clear than by the amount of blood expectorated. The greatest danger to a child with hemoptysis is not exsanguination but rather asphyxiation from aspirated blood. The management of the child with life-threatening hemoptysis is beyond the scope of this chapter. However, if the child has evidence of cardiorespiratory distress, hypotension, orthostatic changes, poor perfusion, pallor, tachypnea, tachycardia, mental status changes, arterial hypoxemia, or hypercarbia, then the stabilization and evaluation of the child should occur simultaneously in a pediatric intensive care unit.

Before summoning the bronchoscopist, echocardiographer, and interventional radiologist and scheduling pulmonary arteriography and radionuclide scanning, the primary care physician must ascertain whether the source of bleeding is indeed within the thorax. Thorough inspection of the oropharynx and nasal passages may identify an upper airway source of bleeding. Infants and young children with hemoptysis may not cough up blood but instead swallow the blood and vomit it later. Therefore, in infants, distinguishing hematemesis from hemoptysis is difficult. Examination of the blood-stained secretions may help differentiate the bleeding site so that it can be established whether the bleeding is from the respiratory tract or not. Table 161-2 describes how to differentiate hemoptysis from bleeding from other sources.

### History

As is the case for any sign or symptom with many possible causes, a detailed history of both pulmonary and nonpulmonary symptoms will often allow a tentative diagnosis to be made. The presumptive diagnosis can then be proved or disproved by the findings of specific laboratory tests and procedures. For a child or adolescent without any preexisting medical condition who displays a first episode of hemoptysis, the most common causes are acute infections of the tracheobronchial tree, pneumonias, and foreign-body aspirations.

**Table 161-2** Differentiation of Hemoptysis From Hematemesis and Upper Airway Hemorrhage<sup>a</sup>

CHARACTERISTIC	HEMOPTYSIS	HEMATEMESIS AND UPPER AIRWAY HEMORRHAGE
pH	Alkaline	Acidic
Color	Bright red	Dark red or brown
Consistency	Clotted, liquid, or frothy	Coffee ground
Symptoms	Cough	Nausea and vomiting
Gram stain	Macrophages	Food particles and epithelial cells

<sup>a</sup>Younger children and infants may swallow blood that originates from the lungs, which may seem to have a nonpulmonary source of bleeding.

Hemoptysis can be the presenting symptom for an autoimmune disorder or other immunologic abnormality, although this circumstance is rare. Travel to or from developing countries and areas that raise sheep may necessitate evaluation for mycobacterial, mycotic, or parasitic lung infections. Recurrent pneumonitis, sinus infections, and chronic sputum production may be indicative of bronchiectasis from CF, foreign-body aspiration, ciliary dyskinesias, or other chronic lung diseases. Other aspects of the history that will help focus the evaluation include recent trauma, easy bruising, changes in urine color, weight loss, arthralgias, previous heart disease or surgery, medication use, substance abuse, family history of bleeding disorders, surgical procedures, pica, fever, pleuritic chest pain, menstrual irregularities, and asthma not responsive to appropriate medical therapy. In adolescents with unusual or perplexing symptoms and normal findings at evaluation, factitious hemoptysis and Münchausen syndrome should also be considered. Factitious hemoptysis has been reported in children who underwent numerous invasive procedures, and, ultimately, the determination was made that these children were biting their oral mucosa to simulate hemoptysis.

### Physical Examination

Physical examination begins with a determination of the vital signs to decide the rapidity at which the examination should be conducted. A thorough inspection of the nasal passages and oropharynx is conducted to rule out a nonpulmonary cause of the hemoptysis. As the examination proceeds caudally, certain findings on inspection and auscultation may suggest a specific diagnosis. Cutaneous telangiectases with a murmur or bruit over the lung fields suggest hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome). Clubbing with or without adventitial breath sounds suggests bronchiectasis. A saddle nose and stridor suggestive of subglottic stenosis are often seen in patients with necrotizing granulomatous vasculitis. A pleuritic rub, acute pleuritic chest pain, and a history of oral contraceptive use or recent abortion suggest a pulmonary embolic event or other pleural-based lesion. Localized homophonous wheezing over a major airway or decreased breath sounds, with or without a cough, suggest an intraluminal obstruction such as an aspirated foreign body. Evidence of trauma to the thorax may be subtle and not always obvious. Thirty percent of children who experience major trauma to

other organ systems will be found to have thoracic trauma as well. Examination of the heart may provide evidence of pulmonary hypertension or a new murmur. Lymphadenopathy and hepatosplenomegaly should raise the possibility of a lymphoproliferative disease with an associated bleeding diathesis.

### Laboratory Evaluation

Numerous laboratory tests may be helpful, but they should be focused depending on the history and physical examination. If the patient has a compromised airway, then arterial blood gas measurement may help in the decision of how quickly the intensive care unit needs to be called. Urinalysis or specific serologic markers will help determine if the child has an immunologic disease that involves the basement membranes of both the kidneys and the lungs. A complete blood count with an eosinophil count may help differentiate a bacterial from a parasitic pneumonia. Although clotting studies are routinely ordered, they will invariably be normal because bleeding disorders do not generally cause spontaneous hemoptysis. Although skin tests for mycobacteria should always be performed, other skin tests, or serologic testing for fungi or other infectious agents, should be guided by clinical acumen. If sputum is produced or bronchoscopy is performed, then these pulmonary fluids should be cultured for bacteria, fungi, ova, parasites, and mycobacteria and stained for the presence of hemosiderin-laden macrophages. If warranted, early-morning gastric aspirates can be cultured and stained for microorganisms and macrophages.

### Imaging Studies

The history and physical examination should allow a tentative diagnosis and help decide what imaging studies or procedures need to be undertaken to make a definitive diagnosis. If the child is stable, then a chest radiograph should be obtained. Any abnormality on a chest film should be considered as a potential source for the hemoptysis, but a normal radiograph does not exclude the thorax as the source of bleeding. In approximately one-third of children with hemoptysis, the initial chest radiographic examination will reveal nothing abnormal. Findings on the chest film that help focus the evaluation include hilar adenopathy, an air-fluid level in an abscess, a mass, a cavitary lesion, mediastinal widening, or alveolar infiltrates. Alveolar infiltrates in a child with hemoptysis are a

common finding with autoimmune diseases that involve the lungs. Thickening of the bronchial walls with ring shadows and tramlines suggests bronchiectasis. If a foreign body is suspected to be the cause, then inspiratory and expiratory films or left and right lateral decubitus films may help localize the foreign body. If the foreign body is present and causes obstruction of an airway, then the side of the thorax that does not deflate normally on expiration or when dependent is the side with the foreign body. If the foreign body is embedded within the mucosa of the airway, or if only partial obstruction is present, then the standard chest radiograph may be normal.

The next imaging studies depend on the presumptive diagnosis because not every child with hemoptysis needs special radiographic studies. If the chest radiograph is normal or does not add any information to that obtained from the history and physical examination, then computed tomography (CT) or high-resolution computed tomography (HRCT) may be contributive. CT is effective for detecting parenchymal disease, and HRCT has replaced bronchography for diagnosing bronchiectasis. CT can identify airway abnormalities, elucidate abnormalities seen on chest radiographs, define mediastinal structures, and help categorize congenital pulmonary malformations and pulmonary vasculitis syndromes. CT may also serve as a road map for subsequent bronchoscopy.

Magnetic resonance imaging (MRI) is useful in looking for congenital vascular malformations and for the differentiation of structures within the mediastinum and hilum. Perhaps in the future MRI will supplant CT in the evaluation of hemoptysis, but for now the advantages of MRI do not outweigh its disadvantages, especially if excessive respiratory motion is present or the child's condition is unstable.

### Bronchoscopy

The timing and need for bronchoscopy, either rigid or flexible, depend on the stability of the child's condition and the suspected cause of the hemoptysis. Not every child with hemoptysis needs to undergo bronchoscopy; research indicates that hemoptysis is rarely the primary indication for bronchoscopy. If a child has rapid and complete resolution of hemoptysis after medical therapy, then bronchoscopy need not be performed. Indications for bronchoscopy include a diagnosis that is in question, massive hemoptysis, or an incomplete response to therapy.

No studies have compared the use of fiberoptic versus rigid bronchoscopy for evaluating hemoptysis in either adults or children. Both instruments can be used to administer therapeutic agents to the airways, sample bronchial fluids, and take biopsy samples. With the rigid bronchoscope, bronchoscopists have complete airway control: they can suction through a larger channel, sample suspicious lesions, and insert packing material to tamponade the bleeding. The rigid bronchoscope is the preferred instrument for removing foreign bodies from the airway. On the other hand, fiberoptic bronchoscopy does not require the use of general anesthesia; the scope is usually passed transnasally (so that the upper airways can also be examined), and it can be easily maneuvered into the

upper lobes and more distal airways. If a child with hemoptysis needs bronchoscopy, then fiberoptic bronchoscopy may be used for the initial evaluation. If an anatomic lesion or foreign body is discovered, then rigid bronchoscopy will be needed.

## HEMOPTYSIS IN THE NEWBORN PERIOD

Neonates who have a variety of congenital defects can develop localized hemoptysis and diffuse pulmonary hemorrhage in the newborn period. Arteriovenous malformations, extralobar sequestration, or hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome) can exhibit in the nursery as respiratory distress or mild to massive hemoptysis. All of these vascular malformations cause bleeding as a result of the abnormal connections between the bronchial and pulmonary circulations. The diagnosis of these lesions is made by CT scan with contrast, and children with these defects need to be hospitalized in a center that has a pediatric surgeon and an interventional radiologist.

Diffuse pulmonary hemorrhage is not an uncommon occurrence in infants of very low birth weight. The more premature the infant, the higher is the likelihood of hemorrhage. The pathogenesis of the diffuse bleeding is thought to be from effects of barotrauma on an immature pulmonary capillary endothelium. The risk for pulmonary hemorrhage increases slightly with the administration of exogenous surfactant therapy. Many nonpulmonary conditions have also been associated with diffuse hemorrhage in premature newborns, including central nervous system insults and coagulation and metabolic defects.

### WHEN TO ADMIT

- Evidence of hemodynamic instability
- Mental status changes
- High suspicion of tuberculosis
- Known heart disease
- Chronic lung disease (eg, CF, ciliary dyskinesias, immunodeficiencies)
- High suspicion of pulmonary neoplasm
- Sickle cell anemia, vaso-occlusive crisis, or acute chest syndrome
- Inability to protect airway
- Risk for pulmonary embolism
- Lung abscess
- Children younger than 1 year
- Foreign-body aspiration
- Pulmonary hypertension

## Chapter 162

# HEPATOMEGALY

Philip O. Ozuah, MD, PhD; Marina Reznik, MD, MS

### DEFINITIONS AND CLINICAL MANIFESTATIONS

Hepatomegaly is an enlargement of the liver resulting from an increase in the number or size of cells and structures within the liver. Although hepatomegaly usually manifests clinically as a palpable liver, not all palpable livers result from hepatomegaly. In healthy children, the liver edge may be palpable up to 2 cm below the right costal margin at the midclavicular line. Clinical estimation of the liver span has a much stronger correlation with hepatomegaly than does reporting the liver projection below the costal margin as a single indicator of liver size. The liver span is the distance between the upper and lower margins of the liver at the right midclavicular line. The upper margin should be determined by percussion and the lower edge by either percussion or palpation. Liver span has a curvilinear relation to age, height, weight, and body surface area. Studies have demonstrated no consistent sex differences in liver size. A normal liver span ranges from 5.9 cm ( $\pm 0.8$  cm) in the first week of life to 6.5 to 8 cm by 15 years of age. The upper edge of liver dullness is usually at the level of the fifth rib in the right midclavicular line. Radiographic assessment of liver size can be a helpful adjunct to the clinical examination. Ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and sulfur colloid scintigraphy have all been demonstrated to measure liver size reliably.

### DIFFERENTIAL DIAGNOSIS

The differential diagnoses of a palpable liver and hepatomegaly are presented in Box 162-1.

#### Palpable Liver Without Hepatomegaly

Several intrathoracic conditions may push the right hemidiaphragm down and thereby result in a palpable liver. For example, asthma, bronchiolitis, and pneumonitis may produce a palpable liver through hyperinflation of the lungs. Tension pneumothorax usually has other accompanying clinical features, including dyspnea, tachycardia, tracheal deviation, and hypotension. Congenital diaphragmatic hernias often manifest in the neonatal period with a scaphoid abdomen and the presence of bowel sounds in the chest. Other thoracic space-occupying lesions also can displace the diaphragm.

Abdominal sepsis with a subdiaphragmatic abscess may push the liver caudally. Riedel lobe is an occasional tongue-like process extending downward from the right lobe of the liver lateral to the gallbladder. A palpable liver without hepatomegaly also may be a normal variant.

#### Palpable Liver With Hepatomegaly

##### Inflammatory Disorders

Inflammatory liver disorders frequently manifest clinically with jaundice and a liver that is firm and tender to palpation. Viral hepatitis (including hepatitis A, B, C, D, and E) may be fulminant or insidious in onset. Hepatitis A may be anicteric in 50% of infected children younger than 4 years and in more than 80% of children younger than 2 years. Bacterial sepsis may result in hepatomegaly as part of a generalized process or a localized liver abscess. Toxic hepatitis may result from exposure to a variety of therapeutic and other chemical agents. Idiopathic neonatal hepatitis occurs with direct hyperbilirubinemia and may be difficult to distinguish clinically from congenital biliary atresia without a liver biopsy. Idiopathic neonatal hepatitis is characterized by marked infiltration with inflammatory cells in contrast to bile duct proliferation found in biliary atresia. Giant cell transformation is found in both conditions. In rare instances, autoimmune diseases such as systemic lupus erythematosus and sarcoidosis may involve the liver, leading to a hepatitis with hepatomegaly.

##### Infiltrative Disorders

Primary or metastatic neoplasia may infiltrate the liver and is often associated with other clinical findings. Malignant hepatic tumors manifest clinically with a hard, palpable liver. Benign tumors include large hemangiomas, which occasionally lead to a platelet consumption coagulopathy (Kasabach-Merritt syndrome) as a result of excessive trapping and destruction of platelets within the vascular bed. Clinically, a bruit may be heard over the liver in patients who have hemangiomas and arteriovenous shunts.

##### Storage Disorders

Several genetic enzyme defects result in excessive accumulation of metabolites in the liver. These conditions produce a smooth, distended liver. Many of these syndromes are also associated with other clinical features besides hepatomegaly. Fat and glycogen accumulation are well-known causes of hepatomegaly. Less frequently, copper accumulation results in Indian childhood cirrhosis or Wilson disease. Indian childhood cirrhosis, caused by genetic and environmental factors, produces jaundice and hepatomegaly predominantly in middle-income, rural Hindu children, but it also has been described in other parts of the world. Its onset is at approximately 1 to 3 years of age, usually with rapid evolution to cirrhosis and hepatic failure if left untreated. This disorder was previously thought to be uniformly fatal, but chelation therapy has shown promising results. Wilson disease, an autosomal recessive inherited disorder of copper metabolism, occurs with hepatomegaly in young children but does not generally manifest clinically until after 5 years of age. Children older than 10 years often have neuropsychiatric symptoms; they may also have hemolytic anemia.  $\alpha_1$ -Antitrypsin deficiency may occur with hepatomegaly, icterus, and acholic stools in the first week of life. Signs of chronic liver disease and portal hypertension are seen in older children.

### BOX 162-1 Differential Diagnosis of a Palpable Liver Without Hepatomegaly and With Hepatomegaly

#### PALPABLE LIVER WITHOUT HEPATOMEGALY

- Downward displacement of right hemidiaphragm
  - Hyperinflated lung (eg, asthma, bronchiolitis, pneumonitis)
  - Tension pneumothorax
  - Congenital diaphragmatic hernia
  - Thoracic tumors
- Subdiaphragmatic lesions (eg, abscess)
- Normal variant
- Aberrant lobe of liver (Riedel lobe)

#### PALPABLE LIVER WITH HEPATOMEGALY

- Inflammatory disorders
  - Viral hepatitis
  - Bacterial hepatitis (eg, abscess, sepsis)
  - Toxic hepatitis (eg, drugs)
  - Neonatal hepatitis
  - Autoimmune hepatitis (eg, systemic lupus erythematosus, sarcoidosis)
- Infiltrative disorders
  - Primary tumors
    - Hepatoblastoma
    - Hepatocellular carcinoma
    - Hemangioma
    - Focal nodular hyperplasia
  - Metastatic tumors
    - Lymphoma
    - Leukemia
    - Neuroblastoma
    - Wilms tumor
    - Histiocytosis
- Storage disorders
  - Fat accumulation
    - Obesity
    - Malnutrition
  - Reye syndrome
  - Cystic fibrosis
  - Diabetes mellitus
  - Lipid infusion
  - Metabolic liver disease
  - Lipidoses (eg, Niemann-Pick, Gaucher, Wolman diseases)
  - Glycogen excess
    - Glycogen storage diseases
    - Infant of mother who has diabetes
    - Beckwith-Wiedemann syndrome
    - Total parenteral nutrition
  - Copper accumulation
    - Indian childhood cirrhosis
    - Wilson disease
  - Miscellaneous
    - $\alpha_1$ -Antitrypsin deficiency
    - Hypervitaminosis A
- Vascular congestion
  - Suprahepatic
    - Congestive heart failure
    - Cardiac tamponade
    - Constrictive pericarditis
  - Intrahepatic
    - Hepatic vein thrombosis (Budd-Chiari syndrome)
    - Hepatic vein web
    - Vascular malformations
      - Cavernous hemangioma
      - Capillary hemangioma
      - Hemangioendothelioma
- Biliary obstruction
  - Congenital biliary atresia
  - Congenital hepatic fibrosis
  - Caroli disease

Excessive ingestion and accumulation of vitamin A can also result in hepatomegaly.

#### Vascular Congestion

Congestive heart failure, cardiac tamponade, and constrictive pericarditis all lead to impaired cardiac filling and pressure backup into the inferior vena cava and portal vein, all of which produce a smooth, distended, and tender liver. Other signs of cardiac decompensation, including dyspnea, cough, chest pain, and tachycardia, are usually present.

Budd-Chiari syndrome may be caused by a thrombus, mass, or web occluding the inferior vena cava or the hepatic veins and tributaries, resulting in an enlarged liver.

Vascular malformations produce hepatomegaly through several mechanisms, including hemorrhage

into the liver or high-output cardiac failure with secondary vascular congestion, or through the size of the malformation itself.

#### Biliary Obstruction

Biliary atresia occurs in approximately 1 of 8,000 births and is the most frequent reason for liver transplantation in children. The bile duct atresia may be extrahepatic, intrahepatic, or a combination thereof. The presence of jaundice, hepatomegaly, and acholic stools beginning during the first months of life in otherwise healthy-appearing infants is characteristic. Extrahepatic atresia can be corrected surgically, and intrahepatic atresia can be treated using the hepatoportoenterostomy procedure of Kasai. Nevertheless, many patients develop cirrhosis and portal hypertension requiring liver transplantation.

Congenital hepatic fibrosis is an autosomal recessive disorder that occurs in childhood with hepatosplenomegaly, portal hypertension, and bleeding esophageal varices. Up to 75% of affected children have associated renal disease. Histologic analysis reveals diffuse periportal and peribulbar fibrosis. Caroli disease is a congenital saccular dilation of intrahepatic bile ducts that is inherited in an autosomal recessive fashion. Symptoms are usually those of acute cholangitis manifesting in late childhood or young adulthood, with fever, icterus, abdominal pain, and a large, tender liver.

## EVALUATION

### Relevant History and Physical Examination

History and physical examination remain the cornerstone of establishing a prompt diagnosis in patients with hepatomegaly. A thorough history that explores not only gastrointestinal symptoms but also pulmonary and cardiac manifestations will often point in the right diagnostic direction. Physical examination of the liver should include an assessment of its size, consistency, texture, and tenderness. In addition, the liver should be auscultated with a stethoscope.

A firm and tender liver suggests an acute inflammatory disorder; a hard liver is often neoplastic. A smooth and exquisitely tender liver is found in conditions that cause vascular distention. Bruits are heard in arteriovenous malformations. Although a palpable liver may be a normal variant, the concomitant physical finding of an enlarged spleen usually suggests significant disease.

### Laboratory Testing and Imaging

Laboratory investigations should be directed at the suspected diagnosis. Liver function studies are usually necessary. The imaging study used most widely is ultrasonography, which is inexpensive, portable, reliable, and quickly obtainable in most settings. Liver masses detected on ultrasonography may be defined further by CT scanning or sulfur colloid scintigraphy. Hepatic angiography may be indicated in the evaluation of suspected vascular tumors. In patients with probable metabolic or genetic disorders, a percutaneous liver biopsy may be necessary to establish a diagnosis. In addition, the definitive diagnosis of a liver abscess can be made by ultrasound or CT-guided percutaneous liver aspiration.

## MANAGEMENT

Treatment should be aimed at the underlying disease entity. Patients with inflammatory hepatitis require supportive care; those who have bacterial infections should receive appropriate antimicrobials. Surgical excision is the definitive treatment for liver tumors. Chemotherapy may be a helpful adjunct in reducing tumor size either preoperatively or postoperatively.

The treatment of metabolic-genetic disorders includes dietary modifications and chelation therapy. Frequent small feedings of a high-protein, complex-carbohydrate diet, including continuous nighttime feeding via gastrostomy tubes, have been used successfully in managing glycogen storage disorders. Early treatment with D-penicillamine can prevent the progression of Wilson disease. In many cases, the

use of zinc acetate has been approved by the US Food and Drug Administration (FDA) for maintenance therapy of patients with Wilson disease, even if presymptomatic.

Exciting new developments have provided optimism for some disease entities for which no treatments were available in the past. For example, a synthetic enzyme, imiglucerase, has been highly effective in the treatment of Gaucher disease. Other recombinant glucocerebrosidases, recently approved by the FDA or pending approval, include vela-glucerase alpha (Shire HGT, Cambridge, MA, USA) and taliglucerase alpha (Protalix Biotherapeutics, Carmiel, Israel; Pfizer, NY, USA). Both successfully completed phase III trials and were proved safe and clinically efficient in the treatment of Gaucher disease. Although Indian childhood cirrhosis was previously thought to be uniformly fatal, chelation therapy with D-penicillamine has been shown to reduce mortality significantly if administered early in the disease.

### WHEN TO REFER

- Hepatomegaly with concomitant splenomegaly
- Palpation of a hard liver
- Hepatomegaly with distended abdominal veins
- Audible bruit over the liver
- Suspicion of malignancy

### WHEN TO ADMIT

- Liver failure
- Impending liver failure

## Chapter 163

# HIGH BLOOD PRESSURE

Jayanthi Chandar, MD; Sarah E. Messiah, PhD, MPH;  
Gaston Zilleruelo, MD; Steven E. Lipshultz, MD

Hypertension is a well-established cause of substantial morbidity and mortality in adults, particularly in the later years of life. However, recent population-based studies have shown that during the past decade, mean blood pressure (BP) has

increased among children and adolescents. Furthermore, recent longitudinal cohort studies have revealed that elevated BP in childhood often continues into adulthood, predicting hypertension in young adulthood, and other studies have documented the familial nature of essential hypertension.

Even mild to moderate elevations of BP in children almost certainly warrant close attention, lifestyle modifications, and possibly therapy. Mild and moderate levels of hypertension in childhood are generally not associated with marked symptoms, but routine screening will identify a fair number of children who have either primary or secondary hypertension. Definitive therapy can decrease later morbidity. All pediatricians should be familiar with the basic aspects of hypertension in children, including the diagnosis of normal and abnormal BP, the causes of high BP, and the treatment options.

## DEFINITION OF HIGH BLOOD PRESSURE IN CHILDREN

The fourth report by the National Heart, Lung, and Blood Institute Task Force on Blood Pressure Control in Children based operational definitions of high BP in children on a combination of values found in healthy children, clinical experience, and consensus among leaders in the field. In children

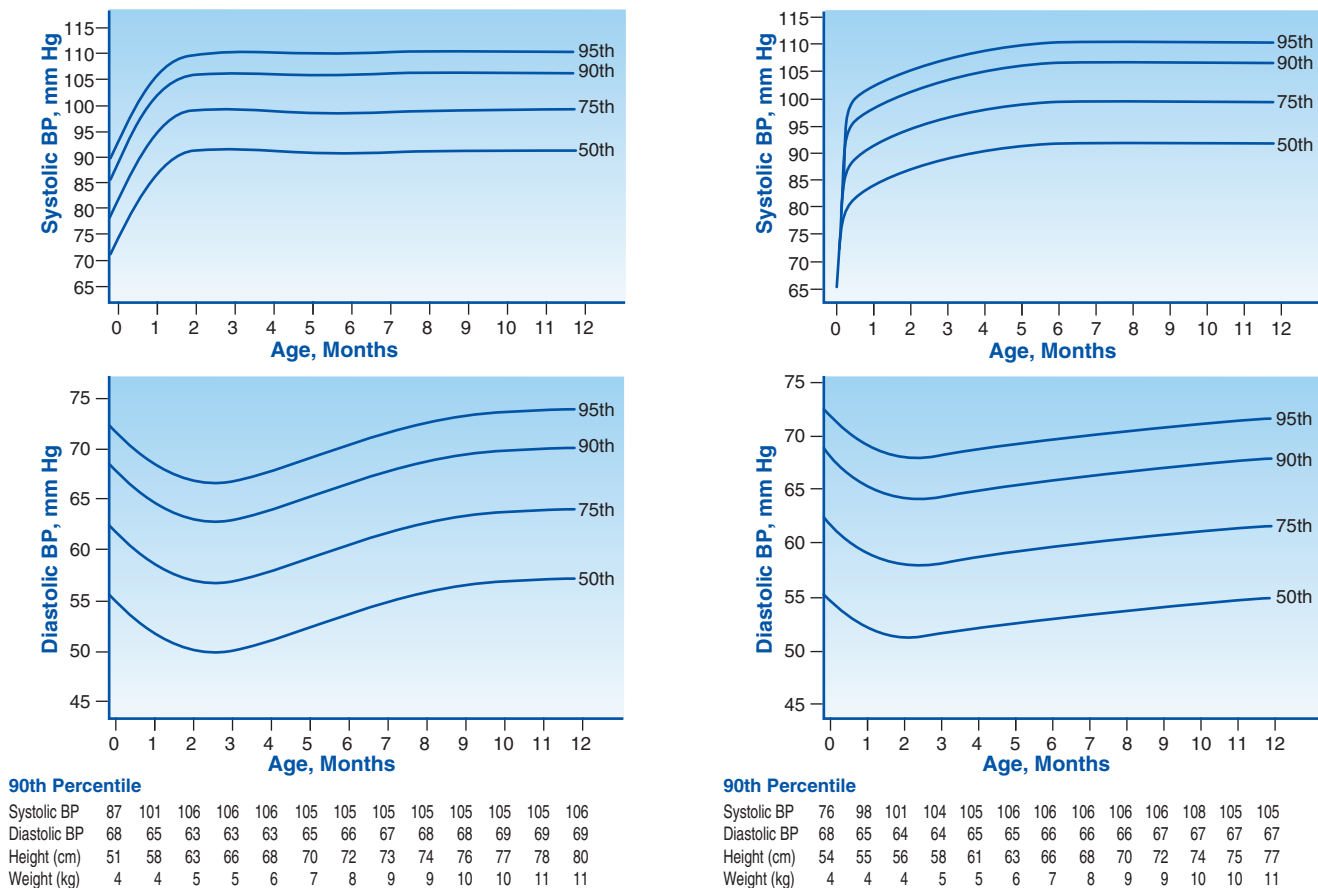

and adolescents, hypertension is defined as an elevated BP that persists on repeated measurements at the 95th percentile or greater for age, height, and sex in a healthy population. Stage 1 hypertension is defined as systolic and diastolic blood pressures that range from about the 95th percentile to 5 mm Hg above the 99th percentile, and stage 2 hypertension refers to systolic and diastolic blood pressures that are 5 mm Hg above the 99th percentile for age, height, and gender. High-normal or prehypertensive BP is defined as a BP between the 90th and 95th percentiles (normal systolic and diastolic BPs are less than the 90th percentile). Severe hypertension (with the risk of end-organ injury) is defined as BP greater than the 99th percentile.

Body size is the single most important determinant of BP in children and adolescents; thus, using accurate height percentiles is critical for correctly estimating BP percentiles (Figure 163-1 and Tables 163-1 and 163-2).

## FACTORS INFLUENCING BLOOD PRESSURE IN CHILDREN

### Age

BP tends to increase throughout the first 2 decades of life. The average systolic BP on the first day of life is 70 mm Hg, and it increases steadily for the next 2 months.

**Figure 163-1** Age-, sex-, height-, and weight-specific percentiles of systolic and diastolic blood pressure in boys (*left*) and girls (*right*) from birth to 12 months of age.

BP, blood pressure.

<sup>a</sup>The 90th, 95th, and 99th percentiles are 1.28, 1.645, and 2.326 standard deviations, respectively, above the mean.From National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents. The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. *Pediatrics*. 2004;114(2):555–572.

It then tends to remain stable until 1 year of age, when it increases until adulthood. Diastolic BP increases slowly for the first week and then declines until 3 months of age. It then increases gradually until 1 year of age, when it returns to the level found in the first week. It again remains steady for the first 5 to 6 years, after which it begins to increase, along with systolic BP. Children tend to maintain the same BP percentile rank relative to their peers as they grow, a pattern that continues through adolescence, supporting the idea that primary hypertension begins in childhood. Normative data have been derived in premature infants in whom the average systolic BP is lower and increases with gestational age.

### Body Size

Body size is a major influence on BP in children. As in adults, the relationship between BP and weight in the teenage years is particularly prominent. Height is also related independently to BP at all ages. However, chronic hypertension is becoming increasingly common in adolescents, primarily because of increases in the prevalence of overweight and obesity. During the past 3 decades, obesity rates have more than doubled for children ages 2 to 5 and 12 to 19 years, and the rates have more than tripled among children ages 6 to 11 years. Presently in the United States, 9 million children older than 6 years are considered obese, with a body mass index (BMI) above the 95th percentile.

### Metabolic Syndrome

Childhood obesity has been associated with a cluster of risk factors for cardiometabolic disease characterized by combinations of insulin resistance, dyslipidemia, and hypertension, which some have termed metabolic syndrome. In turn, this syndrome is associated with the onset of type 2 diabetes and long-term atherosclerotic cardiovascular complications in both childhood and adulthood. Although metabolic syndrome is not currently well-defined, it is increasingly being recognized as a serious complication of childhood obesity. Analysis of the 1999–2006 National Health and Nutrition Examination Surveys found that nearly 1 million US adolescents (about 4% of the total) aged 12 to 19 years have metabolic syndrome; among 8- to 11-year-olds, national prevalence estimates of the syndrome's components ranged from 2% to 9%; and among overweight adolescents, the prevalence of the syndrome is nearly 30%. In addition, obstructive sleep apnea, an independent risk factor for resistant hypertension, is increasingly common in obese children.

Identifying and treating children and adolescents at the earliest stages of chronic disease should be the goal of clinical practice, yet no clear guidelines have been developed for determining the risk for metabolic syndrome or appropriate thresholds for risk factors.

### Ethnicity

In the United States, mean BP in adults differs among racial and ethnic groups. Non-Hispanic black adults have the highest prevalence and incidence of hypertension. However, the age at which BP begins to differ across racial and ethnic groups is unclear. According to the National Heart, Lung, and Blood Institute Growth and Health Study, among other reports, BP is

significantly higher for black girls than for white girls. The prevalence of primary hypertension in black adolescents is higher than that in their nonblack counterparts at lower ranges of BMI. In addition, Mexican American children have a higher mean-adjusted BP than do non-Hispanic white children. In many instances, a higher BMI explains the difference in BP between different ethnic groups. The increase in BMI in children in the United States has accounted for some of the increase in BP; however, other factors such as race contribute to higher BP levels.

### Genetics

Children from families with a history of hypertension tend to have higher BPs than do children from families without such a history, a relationship that generally supports the accepted conclusion that genes influence BP levels. Other cardiovascular risk factors among parents, including disorders of lipid and glucose metabolism, hyperuricemia, poor nutrition, passive smoking, and physical inactivity, are also significantly correlated with the cardiovascular risk factors of their children.

## CAUSES OF HIGH BLOOD PRESSURE IN CHILDREN

### Primary Hypertension

Primary hypertension (previously termed essential hypertension), long known to be the most common cause of hypertension in adults, used to be relatively uncommon in younger children. However, primary hypertension is now occurring more often in children, especially in adolescents. One recent study reported that about half of all children ( $N = 159$ ) seen in a hypertension clinic, albeit a selected population, had primary hypertension, leading to the conclusion that the prevalence of primary hypertension in children is increasing. However, the findings of a tertiary care sample may not generalize to the rest of the population. In this study, the diagnosis of primary hypertension occurred in the presence of obesity (56%) and a positive family history of hypertension (86%).

### Secondary Hypertension

Secondary hypertension is more common in children than in adults, and in most children, hypertension will be secondary to renal or renovascular causes (see Boxes 163-1 and 163-2).

Severe hypertension can occur in neonates and has been reported in 3% of premature infants. Hypertensive neonates often have evidence of congestive heart failure, respiratory distress, feeding difficulties, irritability, lethargy, coma, or seizures. In almost all cases, the hypertension is renal or renovascular in origin, most commonly from renal artery thrombi related to umbilical vessel catheterization.

Another common cause of high BP, especially from birth through the first year of life, is coarctation of the aorta. Medical therapy for the hypertension is usually effective, and the long-term prognosis is surprisingly good. High BP can also occur in infants who have bronchopulmonary dysplasia, patent ductus arteriosus, and increased intracranial pressure. Hypertension has been described in neonates undergoing

**BOX 163-1 Common Causes of Secondary Hypertension in Neonates and Infants**

- Renal artery thrombosis after umbilical artery catheterization
- Coarctation of the aorta
- Congenital renal parenchymal or structural disease
- Renal artery stenosis

**BOX 163-2 Common Causes of Secondary Hypertension in Children and Adolescents**

- Renal disease
- Renal artery stenosis
- Coarctation of the aorta
- Obstructive sleep apnea
- Prolonged treatment with steroids
- Amphetamines
- Mineralocorticoid excess
- Hyperthyroidism
- Pheochromocytoma
- Hypercalcemia
- Neurofibromatosis
- Neurogenic tumors
- Increased intracranial pressure
- Immobilization-induced essential hypertension

extracorporeal membrane oxygenation, possibly caused by volume overload.

Renal parenchymal disease remains the most frequent cause of hypertension in older children and adolescents, accounting for 60% to 80% of cases. Hypertension is evident at the initial diagnosis in almost 80% of all cases of acute poststreptococcal glomerulonephritis, and of those who are normotensive at diagnosis, nearly half will experience hypertension for a brief period during their illness. Hypertension is also associated with other forms of immune complex glomerulonephritis. It can be seen in membranoproliferative glomerulonephritis, systemic lupus erythematosus, diffuse proliferative glomerulonephritis, and immunoglobulin A nephropathy. Hemolytic uremic syndrome also is associated with hypertension, in proportion to the degree of arteriolar thrombosis. Nephrotic syndrome rarely leads to severe hypertension in children unless it is a manifestation of more serious renal disease. Reflux nephropathy, with 5% to 30% of affected children having high BP, is an important cause of hypertension. Hypertension also occurs with polycystic kidney disease and Wilms tumor, but is less common with other renal structural malformations.

Coarctation of the aorta is the most common nonrenal cause of hypertension in childhood, accounting

for 5% to 15% of cases. Hypertension can also occur immediately after repair of the coarctation and for years thereafter. The risk for postoperative hypertension seems to be lower if the lesion is repaired before 5 years of age. Renal artery stenosis, caused by fibromuscular dysplasia, Takayasu arteritis, Williams syndrome, or neurofibromatosis, constitutes 5% to 10% of childhood hypertension and may have marked symptoms caused by end-organ damage (congestive heart failure, left ventricular hypertrophy, retinal changes, and renal impairment).

Endocrinopathies must be considered as potential causes of hypertension in children. The problem may be endogenous, arising from conditions such as hyperthyroidism, hypercalcemia, adrenal cortical hyperplasia, or increased catecholamine production caused by a pheochromocytoma. The problem can also be exogenous, arising from ingestion or abuse of glucocorticoids or other steroids. Because of its association with high BP, the use of oral contraceptives should always be considered as a possible cause of hypertension in adolescent girls.

Various drugs can also be associated with hypertension, particularly sympathomimetics (cocaine, amphetamines, phenylephrine, and pseudoephedrine), and their use should be investigated in older children. Other drugs that can raise BP include nonsteroidal anti-inflammatory drugs, erythropoietin, and cyclosporine.

## MEASURING BLOOD PRESSURE IN CHILDREN

Appropriate BP measurement techniques are important because false-positive readings are more likely when proper care is not taken. All children older than 3 years should have their BP measured. However, certain high-risk groups should have their BP measured before age 3 years (see Box 163-3).

BP should be taken with children and adolescents seated, and with infants supine. In addition, to obtain the most accurate measurements, the child should not have recently ingested stimulant drugs or food and should sit quietly for 5 minutes before the measurement, with his or her back supported and feet on the floor. The BP should preferably be measured in the right arm for consistency and comparison with standard tables. The right arm should be supported, with the elbow at the level of the heart.

An appropriately sized BP cuff should be used to take the measurement. The width of the cuff's bladder must be at least 40% of the circumference at the midpoint of the upper arm, and its length sufficient to cover at least 80% of the circumference of the arm.

The cuff should be inflated to at least 30 mm Hg above the expected systolic BP, although too high a pressure in young children or infants may cause agitation. The stethoscope or Doppler crystal should be placed lightly over the brachial artery in the antecubital fossa, with the elbow remaining at the level of the heart.

Systolic BP is defined as the pressure at the onset of the first Korotkoff sound, and diastolic BP as the pressure at the fifth Korotkoff sound or at the disappearance

### BOX 163-3 Conditions Under Which Children Younger Than 3 Years Should Have Their BP Measured

- Prematurity, very low birth weight, history of neonatal hypertension or other neonatal complications requiring intensive care
- Congenital heart disease (repaired or nonrepaired)
- Recurrent urinary tract infections, hematuria, or proteinuria
- Renal disease or urologic malformations
- Family history of congenital renal disease
- Family history of moderate to severe hypertension
- Solid-organ transplantation
- Malignancy or bone marrow transplantation
- Treatment with drugs known to increase BP
- Other systemic illnesses associated with hypertension (eg, neurofibromatosis, tuberous sclerosis)
- Evidence of elevated intracranial pressure

Adapted from National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents. The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. *Pediatrics*. 2004;114(2):555–572.

or muffling of Korotkoff sounds. In some children, Korotkoff sounds can be heard until cuff pressure drops to 0 mm Hg. Measurements can be repeated with less pressure on the head of the stethoscope. If the fifth Korotkoff sound continues to identify very low pressures, the fourth sound can be recorded instead. BP should be measured twice at each visit, and the average systolic and average diastolic pressures should be recorded.

Automated BP devices can provide serial, noninvasive BP measurements in newborns and infants, in whom auscultation is difficult, and in the intensive care unit, where frequent BP measurements are needed. Automated measurements seem to correlate well with intraarterial readings. These devices are relatively simple to use, and they minimize observer bias and terminal digit preference. However, their reliability in the physician's office is less clear because they require frequent calibration and because reference standards have not been established. These devices may overestimate BP and the incidence of hypertension. Elevated BP obtained on automated devices should be confirmed by auscultation. Thus, in general, auscultation is the recommended method of measuring BP in children.

Ambulatory monitoring has recently been used to help establish the diagnosis of hypertension and to track diurnal variations of BP in older children. The monitors are worn on the arm for 24 hours and measure BP regularly throughout the day and night. Ambulatory monitoring is helpful specifically in evaluating white-coat hypertension, the risk for hypertensive end-organ injury, and efficacy of treatment and drug resistance, and to diagnose masked hypertension and hypotension that may occur with the use of antihypertensive drugs. In addition, ambulatory monitoring can be used to evaluate BP patterns in conditions such as episodic hypertension, chronic kidney disease, diabetes,

and autonomic dysfunction. BP typically decreases by more than 10% during sleep, and the absence of this decrease is strongly associated with masked hypertension and end-organ damage. Systolic and diastolic BPs above the 95th percentile for age, sex, and height in more than 25% of ambulatory measurements are considered abnormal and require treatment. However, ambulatory BP monitoring of children and adolescents should only be used and interpreted by persons experienced in treating pediatric hypertension.

## MECHANISMS OF BLOOD PRESSURE REGULATION

A complete discussion of the complex balance between hormonal and physical factors that regulate BP is beyond the scope of this chapter. Instead, the more important concepts are summarized here.

BP is the product of cardiac output and systemic resistance; therefore, anything that affects heart rate, stroke volume, blood volume, or peripheral resistance will alter BP. Peripheral resistance is affected not only by physical changes but also by the actions of various hormones on a given vascular bed. Angiotensin II, the major end product of the renin-angiotensin system, exerts the most hormonal control over BP. As a potent vasoconstrictor, it increases intravascular volume and is closely related to renal blood flow. Renin, the enzyme that stimulates the production of angiotensin II, is itself stimulated by volume depletion, hypotension, and salt depletion and is inhibited by volume expansion and salt loading. Several other hormonal systems also affect renin release, such as circulating catecholamines, glucagon, and adrenocorticotrophic and parathyroid hormones. Angiotensin II provides feedback that inhibits renin release; mineralocorticoids and antidiuretic hormone do the same.

Drugs can also affect renin release. Vasodilators and diuretics stimulate renin release, whereas mineralocorticoids and beta blockers inhibit it. Other hormonal systems also help regulate BP. Catecholamine secretion increases BP, and in the presence of a pheochromocytoma or neuroblastoma, it can cause severe hypertension. Mineralocorticoids and glucocorticoids affect BP, and adrenal hypertrophy and tumors may lead to severe hypertension. Also, obesity is characterized by increased sympathetic nervous activity and insulin resistance, which result in sodium retention and in increased levels of renin, angiotensin II, and aldosterone.

## DIAGNOSTIC EVALUATION

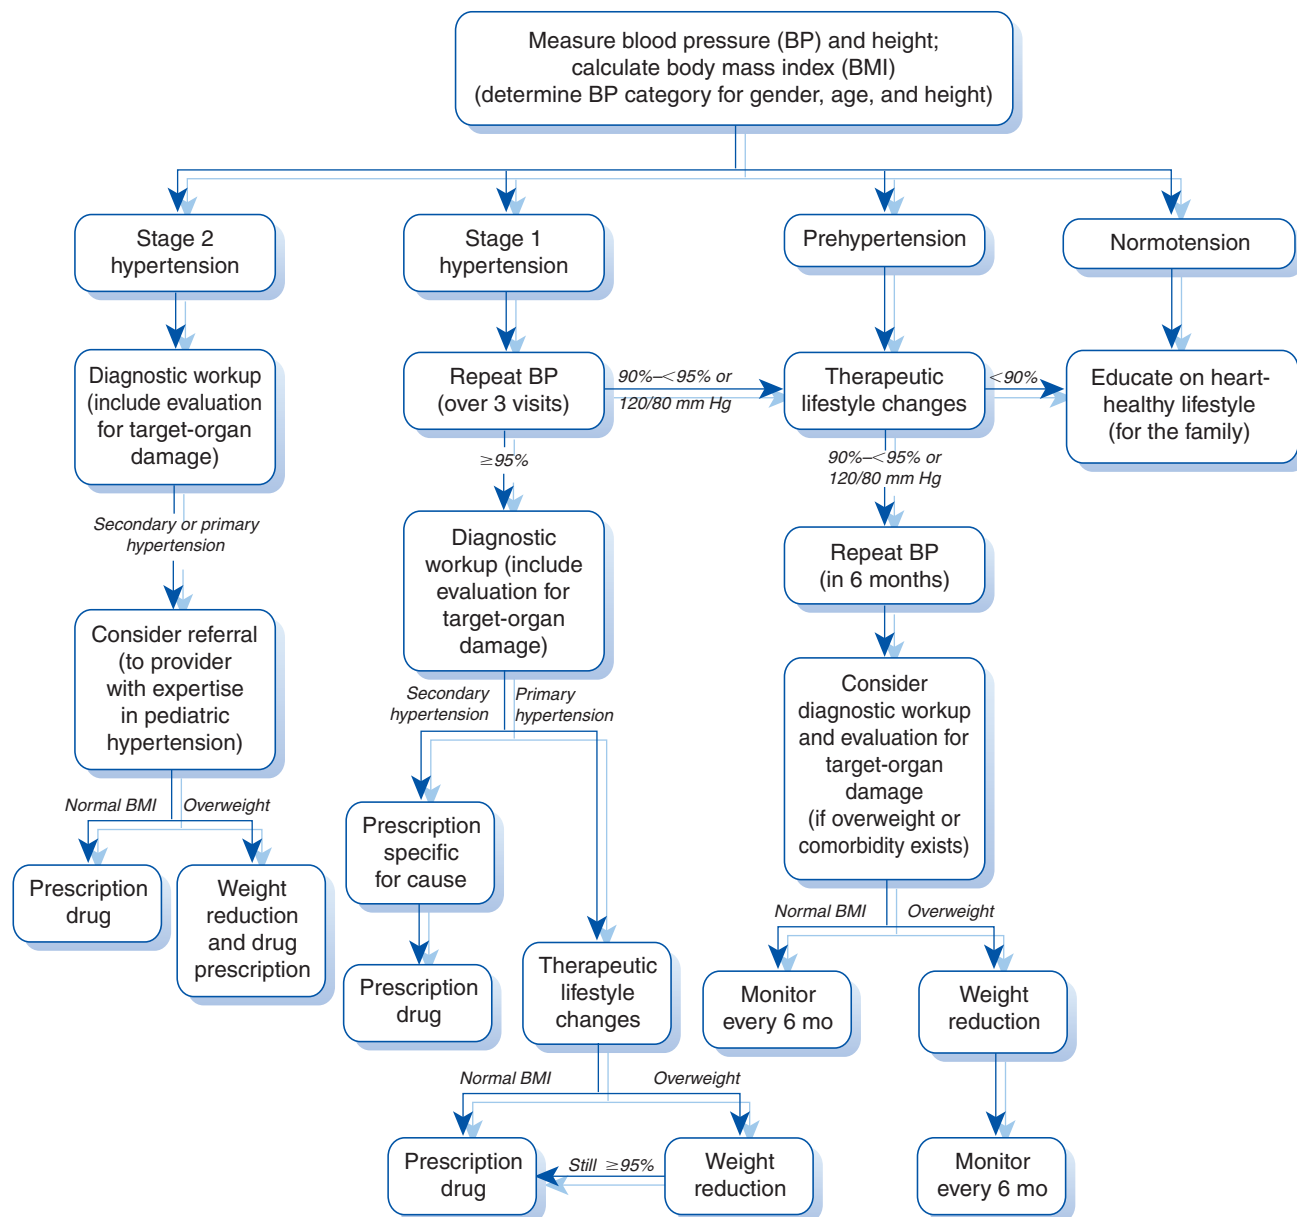

The first step in evaluating a child believed to have hypertension is to conduct a thorough history and physical examination. The medical history should include questions regarding all cardiovascular risk factors, symptoms suggestive of secondary hypertension, and possible target organ damage. In particular, attention should be paid to any history suggesting the recent onset of renal disease or of chronic urinary tract infections. In adolescents, the use of exogenous steroids, oral contraceptives, illicit drugs, tobacco, or alcohol should be specifically determined. A history of prematurity, patent ductus arteriosus, or bronchopulmonary

dysplasia and a positive family history, including age of onset of essential hypertension, systemic disease, or endocrinopathy, may help direct further evaluations. A systems review that includes the details of diet, salt intake, and exercise will be helpful in eliciting reports of symptoms associated with specific diseases that can cause hypertension.

Critical in the physical examination is the careful measurement of BP, as described earlier, with special attention to using an appropriately sized cuff and good technique. BP should be measured in all 4 extremities, and the radial, brachial, and, most important, femoral pulses should be assessed. To identify any abnormalities, a complete examination should include an examination of the optic fundi; calculation of

BMI (weight in kilograms divided by the square of height in meters); auscultation for carotid, abdominal, and femoral bruits; palpation of the thyroid gland; a thorough examination of the heart and lungs; examination of the abdomen for enlarged kidneys, masses, and abnormal aortic pulsation; palpation of the legs for edema and pulses; cutaneous examination for lesions associated with hypertension such as café au lait spots; and a neurologic assessment. These findings will further direct evaluation, which should be a stepwise investigation tailored to the age of the child and to the specific findings. For example, decreased femoral pulses may indicate coarctation of the aorta.

Hypertension can be diagnosed and managed with an algorithm (Figure 163-2). Ideally, BP values should

**Figure 163-2** Algorithm for diagnosing high blood pressure in children. (Modified from National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents. The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. *Pediatrics*. 2004;114[2]:555–572.)

be an average of at least 2 separate measurements or, even better, of measurements obtained on three separate occasions. All children should be screened for possible renal dysfunction by obtaining a urinalysis, complete blood count, serum urea nitrogen, creatinine, and serum electrolyte evaluation that includes glucose. A renal ultrasound may also be appropriate. If the family history is positive for essential hypertension, then a lipid profile that includes high- and low-density lipoprotein cholesterol and triglycerides will help assess cardiovascular risk (see Box 163-4).

If hypertension is severe and the initial diagnostic tests are inconclusive, or if BP remains elevated after initial treatment, more intensive investigations are indicated. If a renal cause is suspected, further imaging of the genitourinary system may be necessary. A stepwise, age-appropriate approach is suggested for evaluation for renovascular hypertension. In the neonate, color Doppler ultrasound of the aorta and renal vessels is a relatively simple, safe, noninvasive, and quick way of detecting aortic, renal venous, and arterial thrombi. This can be performed in conjunction with a renal ultrasound, which is necessary to look for congenital and parenchymal abnormalities. Additional diagnostic tools such as measurement of resistive indices and peak systolic velocities in the renal arteries increase sensitivity and specificity for diagnosing renal artery stenosis.

#### **BOX 163-4 Diagnostic Tests for Hypertension and Its Consequences**

##### **DIAGNOSTIC TESTS**

- Urinalysis
- Complete blood cell count with platelets and blood smear
- Serum electrolytes, blood urea nitrogen, creatinine, calcium, phosphorus, albumin
- Antinuclear antibody, serum C3 complement
- Plasma renin and aldosterone
- Renal ultrasound with Doppler study of renal vessels
- Urinary metanephrine, norepinephrine, and epinephrine
- Thyroid function tests
- Urine toxicology

##### **TESTS FOR END-ORGAN DAMAGE**

- Chest radiograph
- Electrocardiogram
- Echocardiogram
- Ophthalmologic examination

##### **ASSESSMENT OF ASSOCIATED RISK FACTORS**

- Serum lipid profile
- Fasting insulin and glucose
- Serum uric acid

A negative Doppler study, however, does not exclude renovascular hypertension. Nuclear scintigraphy with angiotensin-converting enzyme (ACE) inhibition has moderate sensitivity and specificity. It can be useful to evaluate differential renal function and predict renal functional deterioration with the use of ACE inhibitors.

Technical advances in recent years have improved the quality of images with high-resolution contrast-enhanced computed tomographic (CT) angiography, which can give 3-dimensional views of the renal arteries. The disadvantage is the exposure to radiation. Magnetic resonance angiography with gadolinium is also an alternative but requires sedation or general anesthesia and may not provide adequate spatial resolution compared with CT angiography. Both imaging modalities could still miss stenotic lesions of the renal arteries in small children. The gold standard for diagnosis of renovascular hypertension is digital subtraction angiography in which the visualization of blood vessels is enhanced by digitally subtracting images of background structures.

Plasma renin activity can be used to screen for renovascular hypertension and mineralocorticoid disease. Thyroid function or serum catecholamine tests may be helpful if hyperthyroidism or pheochromocytoma is suspected.

Cardiac evaluation is an important part of the examination. In addition to a thorough physical examination that includes feeling the femoral pulse, electrocardiography and echocardiography may identify coarctation of the aorta and will provide information about left ventricular mass. Left ventricular hypertrophy is the most prominent evidence of target-organ damage. Thus, in children with established hypertension, left ventricular mass should be assessed at diagnosis and periodically thereafter. Formal stress testing can help assess normal and abnormal BP responses to exercise, which might be especially informative in young athletes. Ambulatory BP measurements can help detect hypertension and determine the amount of time each day that BP is elevated.

#### **THERAPY FOR HIGH BLOOD PRESSURE**

The justification for treating children who have marked hypertension comes from the results of adult trials showing that reducing BP has positive effects on cardiovascular status and reduces the risk for target-organ damage. Pediatric studies showing beneficial effects on cardiovascular status are few.

Therapeutic lifestyle changes are generally recommended for children with mild or moderate hypertension. Initiating a low-salt or no-added-salt diet is reasonable because many patients will be salt sensitive. In addition, the intake of fresh vegetables, fruits, fiber, and low-fat dairy products should be increased.

Body size is a major determinant of BP, and weight loss is often associated with reduced systolic and diastolic pressures. Maintaining a normal weight in childhood reduces the likelihood of high BP in adulthood. Weight loss also is associated with decreased BP sensitivity to salt and decreases in other risk factors, such as dyslipidemia and insulin resistance.

Exercise as an adjunct to weight loss often reduces BP even more than weight loss alone. Increasing regular physical activity and decreasing sedentary activities are important in preventing hypertension in childhood and adolescence. Lifestyle modifications are recommended for all stages of hypertension because exercise reduces BP in all individuals regardless of body mass index. When children and adolescents do not respond to lifestyle modifications or have conditions such as stage 2 systemic hypertension, secondary hypertension, or established hypertensive target-organ damage, medications are indicated. Because the long-term effects of antihypertensive therapy in children are not well studied, a definite

indication for drug therapy is needed before starting treatment (see Table 163-3).

All classes of antihypertensive drugs lower BP in children; therefore, the choice of therapy depends on the underlying etiology. It is useful to determine whether hypertension is renin mediated or non-renin mediated. Volume-dependent hypertension as seen in poststreptococcal glomerulonephritis is responsive to diuretics. Diuretics are not desirable in active athletes because of the risk for hypovolemia and hypokalemia. ACE inhibitors and receptor blockers are useful in proteinuric renal disease for controlling hypertension, reducing proteinuria, and slowing progression of kidney disease. They have to be used

**Table 163-3** Antihypertensive Drugs Commonly Used to Manage Chronic Hypertension in Children

DRUG	INITIAL DOSE (mg/kg/day)	MAXIMAL DOSE	INTERVAL (TIMES/DAY)
<b>ACE INHIBITORS</b>			
Benazepril <sup>a</sup>	0.2	40 mg	1
Captopril <sup>b</sup>	0.15–0.5	6 mg/kg/day	3–4
Enalapril <sup>b</sup>	0.08–0.5	40 mg	1–2
Fosinopril <sup>a</sup>	0.1–0.6	40 mg	1
Lisinopril <sup>a</sup>	0.07	40 mg	1
<b>ANGIOTENSIN RECEPTOR BLOCKERS</b>			
Irbesartan <sup>a</sup>			
6–12 yr	2	75–150 mg	1–2
≥13 yr	2	150–300 mg	1–2
Losartan	0.7	100 mg	1–2
Candesartan	0.05–0.4	32 mg	1–2
Valsartan	1.3	160 mg	1
<b>ALPHA AND BETA BLOCKERS</b>			
Labetalol	1–4	1,200 mg	2
Atenolol	0.5–1.2	100 mg	1
Bisoprolol/HCTZ <sup>a</sup>	2.5/6.25 mg/day	10/6.25 mg	1
Metoprolol	1–2	200 mg	1–2
Propranolol	1–4	640 mg	2–4
<b>CALCIUM CHANNEL BLOCKERS</b>			
Amlodipine	0.1–0.6	20 mg	1–2
Felodipine <sup>a</sup>	2.5 mg/day	10 mg	1
Isradipine	0.15–0.2/dose	20 mg	2–4
Extended-release nifedipine	0.25–0.5	120 mg	1
<b>CENTRAL ALPHA-AGONIST</b>			
Clonidine (≥12 yr)	0.05–0.2 mg/day	2.4 mg	2–4
<b>DIURETICS</b>			
HCTZ	1–4	200 mg	1–2
Furosemide	0.5–2	6 mg/kg/dose	2–4
Spironolactone	1–3.3	200 mg	2–4
Amiloride	0.4–0.625	20 mg	1
<b>VASODILATORS</b>			
Hydralazine	0.75–1	200 mg	2–4
Minoxidil	0.1–0.5 mg/kg/dose	20 mg	2

ACE, angiotensin-converting enzyme; HCTZ, hydrochlorothiazide.

<sup>a</sup>Not recommended before age 6 years.

<sup>b</sup>The lowest effective dose of these drugs is used in neonates because it can cause acute deterioration in renal function.

with caution in female adolescents because of the risk for ACE inhibitor fetopathy. Beta blockers and calcium channel blockers can be used in children with hypertension and migraine. Beta blockers should not be used in active athletes because they decrease cardiac contractility, heart rate, and maximum oxygen uptake.

The noncardioselective beta blockers can cause hypoglycemia after intense exercise. They can be problematic for patients who have reactive airway disease or diabetes. Angiotensin blockers and calcium channel blockers have the least adverse effects in the physically active adolescent.

The basic medication strategy is to start with a single drug and assess the response. Additional drugs should be added one at a time, always attempting to target a different mechanism. In primary hypertension, the drug of first choice is usually an ACE inhibitor or a calcium channel blocker. The  $\alpha$ -agonists are generally considered to be second-line drugs. For children who have chronic primary hypertension but no hypertensive target-organ damage, the goal of drug therapy should be to reduce BP to below the 95th percentile for sex, age, and height. For children with chronic renal disease, diabetes, or hypertensive target-organ damage, the goal of therapy should be to reduce BP to below the 90th percentile for sex,

age, and height. Patients with stage 1 hypertension can be monitored every 3 to 6 months. Patients with stage 2 hypertension should be monitored more closely depending on the degree of control. Hypertension should be treated judiciously in patients with elevated intracranial pressure.

Note that ACE inhibitors and angiotensin receptor blockers are teratogenic. Avoidance of pregnancy is suggested in sexually active females.

### ATHLETIC PARTICIPATION BY CHILDREN WITH HYPERTENSION

Children should be encouraged to participate in non-competitive physical activity because regular aerobic exercise reduces both systolic and diastolic BP. Dynamic exercise greatly increases systolic BP and decreases diastolic BP, whereas isometric exercise increases both. Children with stage 2 hypertension need to be cautious about participating in competitive sports with highly static components (see Figure 163-3 and Table 163-4).

The dynamic component is the estimated percentage of maximal oxygen uptake ( $\text{max O}_2$ ). Higher uptake increases cardiac output. The static component is the percentage of maximal voluntary contraction. Higher contractions increase blood pressure.

Increasing Static Component ↑	III. High ( $>50\%$ MVC)	Bobsledding/luge, <sup>a,b</sup> field events (throwing), gymnastics, <sup>a,b</sup> martial arts, <sup>a</sup> sailing, sport climbing, water skiing, <sup>a,b</sup> weight lifting, <sup>a,b</sup>	Body building, <sup>a,b</sup> downhill skiing, <sup>a,b</sup> skateboarding, <sup>a,b</sup> snowboarding, <sup>a,b</sup> wrestling <sup>a,b</sup>	Boxing, <sup>a,c</sup> canoeing/kayaking, cycling, <sup>a,b</sup> decathlon, rowing, speed-skating, <sup>a,b</sup> triathlon <sup>a,b</sup>
	II. Moderate ( $20\%–50\%$ MVC)	Archery, auto racing, <sup>a,b</sup> diving, <sup>a,b</sup> equestrian, <sup>a,b</sup> motorcycling <sup>a,b</sup>	American football, <sup>a</sup> field events (jumping), figure skating, <sup>a</sup> rodeoing, <sup>a,b</sup> rugby, <sup>a</sup> running (sprint), surfing, <sup>a,b</sup> synchronized swimming <sup>b</sup>	Basketball, <sup>a</sup> ice hockey, <sup>a</sup> cross-country skiing (skating technique), lacrosse, <sup>a</sup> running (middle distance), swimming, team handball
	I. Low ( $<20\%$ MVC)	Billiards, bowling, cricket, <sup>d</sup> curling, golf, riflery	Baseball/softball, <sup>a</sup> fencing, table tennis, volleyball	Badminton, cross-country skiing (classic technique), field hockey, <sup>a</sup> orienteering, race walking, racquetball/squash, running (long distance), soccer, <sup>a</sup> tennis
		A. Low ( $<40\%$ $\text{max O}_2$ )	B. Moderate ( $40\%–70\%$ $\text{max O}_2$ )	C. High ( $>70\%$ $\text{max O}_2$ )
		Increasing Dynamic Component →		

**Figure 163-3** Classification of sports. This classification is based on peak static and dynamic components achieved during competition. It should be noted, however, that higher values may be reached during training. The increasing dynamic component is defined in terms of the estimated percent of maximal oxygen uptake ( $\text{max O}_2$ ) achieved and results in an increasing cardiac output. The increasing static component is related to the estimated percent of maximal voluntary contraction (MVC) reached and results in an increasing blood pressure load. The lowest total cardiovascular demands (cardiac output and blood pressure) are shown in **green** and the highest in **red**. **Blue, yellow, and orange** depict low moderate, moderate, and high moderate total cardiovascular demands. <sup>a</sup>Danger of bodily collision. <sup>b</sup>Increased risk if syncope occurs. <sup>c</sup>Participation is not recommended by the American Academy of Pediatrics. <sup>d</sup>The American Academy of Pediatrics classifies cricket as a low-static, moderate dynamic sport. (Adapted with permission from Mitchell JH, Haskell W, Snell P, et al. Task force 8: classification of sports. *J Am Coll Cardiol*. 2005;45(8):1364–1367.)

## HYPERTENSIVE EMERGENCY AND URGENCY

A hypertensive emergency or malignant hypertension is defined as a sudden elevation in blood pressure posing an immediate threat to the integrity of the cardiovascular system, kidneys, or central nervous system. Permanent neurologic damage, blindness, and chronic renal failure are some of the long-term consequences of malignant hypertension. Hypertensive emergency or crisis may occur in individuals previously not known to have hypertension or in those known to have chronic hypertension or kidney disease. Initial treatment should focus on reducing BP to alleviate acute symptoms, not necessarily to make the patient normotensive. Hypertensive emergencies should be treated with an intravenous antihypertensive medication that can steadily reduce BP, decreasing the pressure by no more than 25% over the first 8 hours and then gradually reducing it to normal over the next 24 to 48 hours (see Table 163-5). In contrast, hypertensive urgency is severe hypertension with no acute (or minimal) end-organ damage. It produces less serious symptoms, such as severe headache or vomiting. Urgencies can be treated by either intravenous or oral antihypertensives.

## CONCLUSION

Evidence of a link between the onset of hypertension in childhood and adult morbidity and mortality from end-organ damage is increasing. As pediatricians become more aware of the importance of monitoring BP in childhood and diagnosing hypertension earlier, they have the opportunity to decrease its long-term adverse cardiovascular effects. Even small reductions in BP can improve the health of children and their cardiovascular status later in life. Of equal

importance for physicians is the need to educate parents and children about the health dangers of obesity because this condition has become increasingly prevalent.

### WHEN TO REFER

- Stage 1 hypertension
- Stage 2 hypertension
- Specific conditions requiring referral
- Symptomatic essential hypertension
- Secondary hypertension
- Hypertension with diabetes
- Evidence of target-organ damage (left ventricular hypertrophy)
- Neonatal hypertension

### WHEN TO ADMIT

- Hypertensive emergencies (associated with manifestations in other organs)
- Hypertensive urgencies (severe BP elevation without other organ involvement)
- Acute glomerular diseases
- Poststreptococcal glomerulonephritis
- Hemolytic uremic syndrome
- Renal artery stenosis
- Fibromuscular dysplasia
- Previous umbilical artery catheter
- Neurofibromatosis
- Pheochromocytoma
- Coarctation of aorta
- Noncompliance with current antihypertensive medication
- Cocaine toxicity
- Dialysis patients with excessive volume expansion

**Table 163-4** Exercise Guidelines for Adolescents With Hypertension, by Intervention or Evaluation

	INTERVENTION	EXERCISE
Prehypertension	Daily physical activity Well-balanced diet Weight management Caffeine, drugs, tobacco, and stimulant use to be reviewed BP check every 6 months	No restriction Can participate in competitive athletic sports Encourage aerobic exercises
Stage 1 hypertension	Evaluation for end-organ damage Lifestyle modifications as with prehypertension	No restriction Can participate in competitive athletic sports if no end-organ damage Encourage aerobic exercises
Stage 2 hypertension	Evaluation for end-organ damage Evaluation by medical specialist Lifestyle modifications as with prehypertension Pharmacologic treatment	Restriction from high static sports Eligibility for competitive sports depends on extent of cardiac disease Encourage aerobic exercises, with intensity determined by extent of cardiac disease

**Table 163-5** Drugs Used to Treat Hypertensive Emergencies and Hypertensive Urgencies

HYPERTENSIVE EMERGENCY	ROUTE	DOSE	ADVERSE EFFECTS
Sodium nitroprusside	IV	0.5–8 mcg/kg/min	Thiocyanate toxicity with decreased renal function
Nicardipine	IV	1–3 mcg/kg/min	Headache; increased intracranial pressure
Labetalol	IV: infusion-bolus	0.25–3 mg/kg/hr; 0.2–1 mg/kg/dose Maximum, 40 mg/dose	Use with caution in hyperkalemia and congestive heart failure
Fenoldopam	IV	0.2–1.2 mcg/kg/min	Tachycardia; increased intracranial pressure
Enalaprilat	IV	0.005–0.01 mg/kg/dose	Acute renal failure and hyperkalemia
Hydralazine	IV	0.1–0.6 mg/kg/dose q4–6hr	Tachycardia, flushing, lupus-like syndrome
Nifedipine	Sublingual	0.1–0.25 mg/kg/dose Maximum 10 mg	Precipitous drop in blood pressure; tachycardia; headache
Esmolol	IV	Bolus 100–500 mcg over 1 min; 25–100 mcg/kg/min; can increase to 500 mcg/kg/min	Can cause congestive heart failure, bradycardia, and bronchospasm; contraindicated in cocaine toxicity
Clevidipine	IV	0.5–3.5 mcg/kg/min	Contraindicated in lipid disorders, egg and soy allergy
Phentolamine	IV	0.1–0.2 mg/kg/dose; not to exceed 5 mg/dose (0.05–0.1 mg/kg/dose for treatment of hypertension during surgery)	Orthostatic hypotension, tachycardia, gastrointestinal disturbances
<b>HYPERTENSIVE URGENCY</b>			
Furosemide	IV/PO	1–2 mg/kg/dose	Electrolyte disturbances
Clonidine	PO	0.05–0.3 mg	Rebound hypertension; sedation
Minoxidil	PO	0.1–0.2 mg/kg/dose Maximum 10 mg	Pericardial effusion

IV, intravenous; PO, by mouth.

## TOOLS FOR PRACTICE

### Engaging Patient and Family

## Chapter 164

HIRSUTISM, HYPERTRICHOSIS,  
AND PRECOCIOUS SEXUAL  
HAIR DEVELOPMENT

Genna W. Klein, MD; Mariam Gangat, MD

## INTRODUCTION

The extent, distribution, and character of body hair depend on age, sex, ethnicity, and genetics. When evaluating a child or adolescent for the presence of body hair, understanding the history, physiology of the hair follicle, and hair development is essential in determining if the appearance of hair warrants immediate investigation, expectant management, or reassurance.

## BACKGROUND

## Definitions

*Hirsutism* is the presence of excessive terminal hair in androgen dependent and male pattern areas (especially in females). *Hypertrichosis* is excess hair growth, not limited to androgen-sensitive areas, and can be generalized or localized.

*Virilization* (or masculinization) is a result of (usually pathologic) androgen overproduction, with signs including clitoral or phallic enlargement, masculine body habitus, and deepening of the voice. *Pubarche* and *adrenarche*, although at times used interchangeably, more precisely refer to the onset of sexual hair noted on clinical examination and the biochemical rise of adrenal androgens, respectively. *Hyperandrogenism* is the presence of elevated androgens, manifested either clinically by hirsutism, virilization, acne, male-patterned baldness, or biochemically with elevated androgen levels.

## The Hair Follicle

The human body is covered by 5 million hair follicles. The only areas free of hair are the lips, palms, and soles. There are 3 main types of human hair, which are present at different times and at different locations in the human life cycle: lanugo, vellus, and terminal hair types. Lanugo hair sheds during fetal life, and is followed postnatally by vellus hair. Vellus hair (fine, short, and usually lightly pigmented or nonpigmented), is normally seen over the face and arms of children. Terminal hair (thicker, longer and pigmented), is normally found on the scalp, eyebrows, and eyelashes from the time of birth. Hair growth involves 3 asynchronous cycles: growth (anagen phase), rapid involution (catagen phase), and resting (telogen phase). The anagen phase comprises 8% to 85% of the cycle and determines the length and diameter of hair.

Androgens are the primary hormones involved in hair growth, regulating the prolongation of the anagen phase and transformation of vellus to terminal hairs. This occurs first during puberty in androgen-sensitive areas. Paradoxically, the same androgens

cause miniaturization or the transformation of terminal hair to vellus hair on specific areas of the scalp in genetically susceptible individuals, causing male-pattern alopecia (Figure 164-1).

The primary androgen affecting hair growth is testosterone. In normal pubertal females, up to 50% of testosterone production is from the ovaries and adrenal glands. The remainder is derived from peripheral conversion of weaker androgens to testosterone in adipose tissue and skin. Most of the testosterone in the circulation is bound to albumin (lower affinity) or sex hormone binding globulin (SHBG) (higher affinity); SHBG is therefore the primary regulator of free testosterone activity. Within hair follicles, type II 5 $\alpha$ -reductase regulates the conversion of testosterone to dihydrotestosterone (DHT), a more potent androgen because of its higher affinity for the nuclear androgen receptor.

INITIAL EVALUATION OF HAIR  
GROWTH

The evaluation of a patient with complaints of excess hair begins with a careful history and physical examination with specific points relevant to the chief complaint (Box 164-1).

In a preadolescent child, the chief complaint is usually that of body hair or odor. In an adolescent patient, the primary complaint depends on sex. Females typically complain of menstrual irregularities or dermatological manifestations of hyperandrogenism, including severe acne, hirsutism, or androgenic alopecia. Adolescent males come to attention much less frequently unless virilization is rapidly progressive or clinical signs such as alopecia or acne are excessive.

## HYPERTRICHOSIS

## Presentation

The initial task on examination is to differentiate between true sexual hair and hypertrichosis. The former will be dark, coarse, terminal hair that is limited to androgen-dependent regions, while hypertrichosis refers to excess hair growth relative to persons of the same age, sex, and ethnicity but excluding androgen-induced hair growth. If true sexual hair is abnormally present, androgen levels should be measured and, if elevated, the source of hyperandrogenism should be investigated (see Hyperandrogenism).

## Classification

Hypertrichosis is described based on type of hair (lanugo, vellus, or terminal), age of onset (congenital or acquired), distribution (generalized or circumscribed), and location (forehead, ear, neck, back). Although hypertrichosis is uncommon in children, there are many causes and associated conditions, some of which are listed in Box 164-2.

Classification of the different forms of congenital generalized hypertrichosis is difficult given its rarity and overlap of features. For example, *universal congenital hypertrichosis* is often used interchangeably with *Ambras syndrome*, characterized by extremely long vellus hair growth over the entire body (except

**Figure 164-1** Depending on location and androgen level, the prepubertal vellus hair follicle is transformed into a terminal hair follicle or adult sebaceous hair follicle. Scalp terminal hair follicles under androgen exposure can transform back to a vellus type hair follicle. (Reprinted with permission from Rosenfield RL. *Hirsutism*. N Engl J Med. 2005;353:2578–2588.)

palms, soles, and mucosae). Other experts think that Ambras syndrome is a separate entity. A careful examination with attention to the hair type and distribution is critical in classification. The mode of inheritance in most cases is autosomal dominant, although families with apparent X-linked transmission have been described. In a separate form, *congenital hypertrichosis lanuginosa*, affected infants present at birth with generalized homogeneous lanugo hair, which progressively sheds over the first year of life. The mode of inheritance is autosomal dominant although sporadic cases have been reported.

While the above types are rare, an interesting more common form of hypertrichosis is *prepubertal hypertrichosis*, in which the hair is noted at birth and progresses, with a predilection for (terminal) hair growth on the forehead, eyebrows, upper back, and upper limbs. Circumscribed forms of hypertrichosis also exist. An example of such is *lumbosacral hypertrichosis*, which, if seen on the newborn examination, should prompt an expeditious evaluation for an occult spinal dysraphism. Of note, hypertrichosis can be an early manifestation of pubarche, so the prepubertal patient should be observed for progression of the hair development specific to androgen-dependent areas.

### Treatment

Hypertrichosis can be a source of embarrassment for affected children and adolescents. Patients should be counseled that different treatment options are favored for different ages, types of hair, and body locations, but that all treatments have their limitations, pros, and cons. Treatments can be divided into different categories: physical cosmetic interventions (bleaching, waxing, plucking, trimming, shaving, chemical depilatories, electrolysis); light sources and lasers (of which there are different types); and pharmacological treatment. Further discussion on treatment modalities can be found in the discussion on *hirsutism* below. It is important to consider, however, that since hypertrichosis is androgen independent, antiandrogen therapies are not indicated for its treatment.

### HYPERANDROGENISM

When the history and physical examination are consistent with increased production of androgens, hormonal levels should be drawn to help determine the source. Causes can be broadly divided into the location of hormone production: adrenal, gonadal, tumor,

### BOX 164-1 Essential Elements in the History and Physical Examination for Complaint of Excess Hair

#### HISTORY

- General
  - Current age
  - Ethnicity
  - History of weight change
  - Height acceleration
- Hair Growth Description
  - Age of onset
  - Progression of hair growth
  - Location/distribution of hair
- Presence of Other Premature/Abnormal Pubertal Features (Body Odor, Irregular Menses)
- Medical Problems
  - Neurologic conditions
  - Developmental history

- Phenytoin
- Cyclosporine
- Streptomycin
- Minoxidil

or exogenous. Exogenous sources include androgenic medications and anabolic steroids.

#### Adrenal Hyperandrogenism

##### Adrenal Anatomy and Adrenarche

The adrenal cortex comprises 3 zones, each responsible for a different hormone pathway. The zona glomerulosa synthesizes aldosterone under regulation of the renin-angiotensin system. The zona fasciculata (glucocorticoid synthesis) and the zona reticularis (androgen synthesis) are regulated by the hypothalamic-pituitary-adrenal (HPA) axis. Corticotropin-releasing hormone (CRH) from the hypothalamus stimulates secretion of adrenocorticotrophic hormone (ACTH) from the pituitary gland, which in turn stimulates the adrenal gland. *Adrenarche* is characterized by the maturation of the zona reticularis, leading to increased androgen production and the appearance of pubic hair (*pubarche*). The main androgens derived from the adrenal glands are dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEAS), androstenedione, and testosterone. Adrenarche has a role in sexual maturation; however, it occurs independently from gonadotropin-dependent puberty.

##### Premature Adrenarche

*Premature adrenarche* refers to the earlier than normal timing of this process: before age 8 years in girls and age 9 in boys. However, there is racial and ethnic

variation in the age at which puberty begins in normal children. Premature adrenarche is seen more commonly in females and black children. It has also been associated with fetal growth restriction, as seen in small for gestational age (SGA) babies and in prematurity. The concept of fetal programming and the association of pre- and post-natal weight gain with premature adrenarche, the development of obesity, metabolic syndrome, and PCOS offers attractive, yet incompletely understood mechanisms whereby nutritional, hormonal (GH-IGF system and insulin, for example) and epigenetic phenomena might link early processes with subsequent disease.

#### **PRESENTATION AND DIFFERENTIAL DIAGNOSES.**

These children usually present with pubic hair, initially noted perianally in girls and at the base of the penis in boys. Associated findings can include axillary hair and odor, oily skin, or mild acne. Signs of virilization are absent. Transient height acceleration and advancement of bone age may be present; however, final adult height is usually unaffected in cases in which the premature adrenarche is deemed benign (once other causes of premature hair development are excluded). Exposure to an exogenous hormone or drug must be ruled out because premature adrenarche caused by exogenous sources is reversible with removal of the source. Examples of exogenous causes include a family member who is using a testosterone gel without taking proper precautions for close contacts. Of more concern, premature adrenarche may be the first sign of a serious underlying disorder such as an androgen-secreting adrenal tumor or congenital adrenal hyperplasia (CAH). In these conditions, signs of virilization can be present and the bone age is significantly advanced.

**CONGENITAL ADRENAL HYPERPLASIA.** Congenital adrenal hyperplasia represents a group of autosomal recessive disorders involving a deficiency in 1 of the enzymes in adrenal steroid synthesis, leading to impaired cortisol production and increased ACTH production. Shunting of precursors proximal to the enzymatic block results in increased androgen production. The disease manifestations vary clinically and biochemically with each specific enzyme deficiency. The most common cause is 21-hydroxylase deficiency (mutations in the CYP21B gene located on chromosome 6) leading to decreased aldosterone and cortisol and increased production of androstenedione and testosterone. Although the classic form is usually diagnosed in infancy with salt-wasting in boys and ambiguous genitalia plus salt wasting in girls, a *non-classic 21-hydroxylase deficiency* typically presents later in life, with premature adrenarche, hirsutism, or menstrual abnormalities.

#### **Evaluation and Treatment**

If the findings are consistent with sexual hair development (with or without axillary hair, axillary odor, or acne) without any rapid progression, signs of virilization, or signs of true puberty (testicular enlargement in boys and breast development in girls), close follow-up is recommended. Baseline adrenal hormone levels (DHEA, DHEAS, androstenedione, testosterone, 17-hydroxyprogesterone) as well as a bone age

(radiograph of left hand and wrist) may be performed. In children with premature adrenarche, androgen levels are in the early-pubertal range and the bone age is usually within 2 standard deviations of chronological age.

If progression of pubic hair is rapid, signs of virilization are present, or there is moderate elevation of androgen levels or advancement of bone age, an ACTH stimulation test is warranted to rule out non-classical (or late-onset) CAH. Markedly elevated androgen levels or significant advancement of bone age suggests an androgen-producing adrenal or gonadal tumor. If a tumor is suspected, ultrasound or MRI for localization is necessary. Further, if there are signs of true pubertal development, other baseline or stimulation tests to evaluate the hypothalamic-pituitary-gonadal (HPG) axis as well as hypothalamic-pituitary imaging may be necessary. The evaluation and treatment of true precocious puberty will be discussed briefly below and in Chapter 185, Puberty: Normal and Abnormal.

Once a careful evaluation excludes these other conditions, reassurance and continued follow-up of growth and pubertal progression is necessary to make sure that the initial complaints and investigations do not herald a more serious condition. No specific medical treatment is indicated for premature adrenarche. Although premature adrenarche has been characterized as a benign condition (with many sources referring to it as *benign premature adrenarche*), studies in girls have shown associations with conditions such as PCOS and metabolic syndrome. Obesity and acanthosis nigricans are more common in patients with premature adrenarche. Offspring of women with PCOS are at higher risk for premature adrenarche, and brothers of women with PCOS have been found to have higher levels of DHEAS than brothers of unaffected women, suggesting a common cause or risk factor. These findings also lend support to a role for both adrenal and ovarian hyperandrogenism in PCOS, as opposed to it being merely an ovarian process (see section on PCOS). Although these associations among pre- and postnatal growth patterns, obesity, adrenarche, hyperandrogenism, metabolic derangements, and PCOS phenotypes have led to numerous hypotheses regarding common underlying hormonal mechanisms, a single cause remains elusive.

#### **Gonadal Hyperandrogenism**

The differential diagnosis of premature pubarche is age-dependent and may be the presenting sign of a more serious underlying endocrinopathy.

#### **Precocious Puberty**

Precocious puberty can be generally divided into gonadotropin-dependent or gonadotropin-independent precocity.

*Gonadotropin-dependent*, also referred to as *central* or *true* precocious puberty, results from abnormalities of the central nervous system that disrupt the balance between inhibitory and stimulatory factors. These abnormalities include congenital malformations, tumors, and acquired causes such as trauma, infection, surgery, radiation, or chemotherapy. A unique congenital

malformation is hypothalamic hamartoma, which is ectopically located neural tissue containing gonadotropin-releasing hormone (GnRH) secretory neurons. For most affected females, no specific cause of central precocious puberty can be identified, and precocity is therefore classified as idiopathic. GnRH agonists are the mainstay of treatment for central precocious puberty. The increased potency and continuous stimulation desensitizes the pituitary to stimulation from endogenous GnRH, thus halting further progression of puberty.

*Gonadotropin-independent* precocious puberty can be caused by gonadal tumors, McCune-Albright syndrome, and in males by familial testotoxicosis—a disorder caused by a missense mutation of the luteinizing hormone (LH) receptor. Peripheral precocious puberty can induce maturation of the HPG axis, and secondarily lead to true central precocity.

### Infancy

In the neonatal period, there is activation of the HPG axis, leading to androgen production. Peak testosterone production between 1 to 3 months of age coupled with a transient increase in the sensitivity of sexual hair follicles is thought to cause the appearance of pubic hair in the first few months of life. The pubic hair tends to occur in atypical locations—on the mons pubis in girls and on the scrotum in boys; it generally regresses spontaneously.

### Young Child

While generally not the presenting sign of normal central puberty, sexual hair can precede the initial signs of true puberty in up to 20% of normal boys and girls. Therefore, *premature adrenarche* may be the presenting sign of *premature central precocious puberty* (CPP), defined as occurring before age 8 years in girls and 9 years in boys. Chapter 185, Puberty: Normal and Abnormal, reviews pubertal development in normal and abnormal states. Briefly, puberty is the process of physical changes leading to sexual maturity, reproductive capability, and completion of skeletal growth. The process is initiated by *gonadarche* or reactivation of the HPG axis. The HPG axis is regulated by central inhibitory and stimulatory neurotransmitters, as well as peripheral factors such as nutrition and body mass composition. Increased pulsatile release of GnRH from the arcuate nucleus of the hypothalamus acts on the pituitary to stimulate LH and follicle-stimulating hormone (FSH) production. In females, LH acts on the ovarian theca cells and stimulates androgen production. Testosterone diffuses to the nearby granulosa cells where FSH stimulates aromatase conversion of testosterone to estrogen. In males, LH acts on the Leydig cells to stimulate testosterone production while FSH acts on the Sertoli cells to initiate and maintain spermatogenesis.

In girls, breast bud development (*thelarche*) is typically the initial physical change in puberty, which is then followed by the appearance of pubic hair. Height acceleration or growth spurt occurs early in girls, always preceding menarche. In boys, testicular enlargement (>3 mL in volume) is generally the first sign of puberty, followed by penile enlargement, and

development of pubic hair. The growth spurt occurs later in boys. A careful physical examination at the time of initial consultation, as well as continued follow-up for the development of other pubertal signs is crucial in determining if the child has isolated adrenarche or the evolution of CPP.

### Adolescent Female

In the adolescent female presenting with signs of hyperandrogenism, the differential diagnosis includes PCOS, idiopathic hirsutism, nonclassical CAH, exogenous exposure, or tumor. The diagnostics of the latter 3 conditions have been discussed previously.

**POLYCYSTIC OVARY SYNDROME.** Polycystic ovary syndrome (PCOS) was first described by Stein and Leventhal in 1935. It is the most common endocrine disorder affecting adolescent females and women of childbearing age. Although a single cause continues to elude scientists, much has been discovered regarding contributing factors and comorbidities. The diagnostic criteria have been adjusted and remain variable given different expert panel consensus statements. This, as well as imprecision with androgen assays, has made determination of true prevalence difficult. Most endocrinologists accept menstrual irregularities as the symptom of anovulation, combined with either biochemical or clinical evidence of ovarian hyperandrogenism as the pillars of diagnosis of PCOS. Although polycystic ovaries can support the diagnosis of PCOS, their absence does not rule out the diagnosis. As with the workup of the younger child for premature pubarche, it is imperative to exclude other causes of hyperandrogenism, such as exogenous exposure, tumor, and congenital adrenal hyperplasia, among others, prior to diagnosing a patient with PCOS. Further, other endocrinopathies can masquerade as PCOS, such as severe hypothyroidism and hypercortisolism.

PCOS in adolescence can manifest differently than in adult women. Whereas the chief complaint bringing the adult woman to medical attention may be menstrual irregularity or infertility, adolescent females might be more troubled by excess hair, acne, male-pattern alopecia, or menstrual irregularities, including even primary amenorrhea in some. Further, adolescent females with menstrual irregularities or weight gain and acne might be falsely led to believe that these findings are merely physiologic changes associated with pubertal development. This can lead to a delay in medical attention, evaluation, and treatment, as well as a negative effect on self-esteem.

PCOS is likely a polygenic, multifactorial condition. Multiple associated symptoms and biochemical derangements have been regarded as common to most females with PCOS. While obesity and insulin resistance, for example, play a role in many patients, there are lean women with PCOS as well. Fetal origins of PCOS have been studied, with attention to exposures in utero and the subsequent development of insulin resistance and hyperandrogenism, as in the child with premature adrenarche. Further, children born SGA have an increased risk for PCOS. Ovarian hyperandrogenism is a feature in PCOS, with the contribution of adrenal hyperandrogenism as well. The ovarian

theca cells produce weak androgens in response to stimulation by LH by the pituitary gland. In nonpathological states, the granulosa cells, under control of FSH, aromatize the androgens to estrogens. In PCOS an imbalance of LH/FSH leads to a decreased ability to aromatize excess androgen, and failure of the establishment of a dominant follicle, thus resulting in anovulation.

Although insulin resistance is a fundamental component of PCOS, it is unknown whether it causes, exacerbates, or functions as a marker for the condition. Females with PCOS are more insulin resistant than weight-matched females without PCOS. Whereas the liver, muscle, and adipose tissues are resistant to insulin in predisposed hosts, the ovary and adrenal glands maintain sensitivity to insulin. This results in enhanced ovarian hyperandrogenemia. Hyperinsulinism also decreases the level of sex hormone binding globulin (SHBG), which in turn increases the level of available free testosterone.

The manifestation of PCOS is variable across ages and ethnicities, and even within the individual. As mentioned, menstrual irregularities implying anovulation and clinical or biochemical hyperandrogenism are cardinal features. It is important to note that some girls and women with menstrual irregularity do ovulate, and conversely, some girls and women who bleed regularly are not experiencing ovulatory cycles. Most often, however, the presentation related to menses is oligomenorrhea or secondary amenorrhea, although primary amenorrhea and dysfunctional uterine bleeding are possible complaints as well.

The evaluation of a female suspected of having PCOS begins with a careful history and physical examination. Family history of hormonal disorders, infertility, hirsutism, or unexplained newborn demise (unrecognized congenital adrenal hyperplasia with adrenal crisis) should be explored. A complete past medical history, including birth data (for SGA), medications, and exposures is important, along with the timing of puberty and menstrual history. The presence of other findings related to the differential diagnosis of menstrual irregularities should be sought: disordered eating, large weight fluctuations, pregnancy, symptoms of thyroid disease, galactorrhea, and so on. The tempo of physical changes, including menstrual irregularities, and dermatological or other manifestations of hyperandrogenemia, if present, is crucial to determine if the process is gradual as opposed to sudden and rapidly progressive. The latter is more consistent with an exposure or an androgen-secreting tumor, and may be accompanied by more significant signs of virilization, including voice deepening and clitoromegaly, which are only rarely seen in PCOS.

A complete physical examination is warranted to evaluate a female with menstrual irregularities, including a blood pressure check, body mass index measurement, careful inspection of optic discs for papilledema, skin for acanthosis nigricans, palpation of the thyroid, and breast examination for galactorrhea. Furthermore, specific attention should be given to the dermatological signs of hyperandrogenism, including acne (severity, location, extent), alopecia, and hirsutism. The modified Ferriman-Gallwey score is a widely

accepted method of quantifying hirsutism. This system estimates the amount of terminal hair in 9 areas: upper lip, chin, arms, thighs, chest, and upper and lower abdomen and back. Each area is assigned a score of 0 (absent) to 4 (extensive hair growth visible); therefore, the total score can range from 0 to 36. A score of 8 or greater indicates hirsutism; 8 to 15 indicates moderate hirsutism and greater than 15 indicates severe hirsutism (Figure 164-2).

Although widely used, this system has several limitations including the subjective nature of the assessment, inability to account for focal hirsutism, and lack of population based data that take into account racial and ethnic differences in body hair. Examination of the genitalia for clitoromegaly as well as the presence of estrogenized vaginal mucosa also should be done.

The laboratory evaluation of a woman suspected of having PCOS will be driven by the physician's index of suspicion and whether a previous workup for menstrual irregularities has been performed. If the patient has not been evaluated in the past, the full complement of studies may include a complete blood count and metabolic profile, LH, FSH, prolactin, thyroid function tests, pregnancy test, estradiol, and chromosomal analysis. Free testosterone is the single most helpful test in the diagnosis of PCOS. Alternatively, a total testosterone test with SHBG level can be done. Testosterone assays have been notorious for lack of standardization and precision, especially in the lower concentrations that are expected in women. Tandem mass spectrometry is available through commercial laboratories, and should be used if possible. DHEAS and androstenedione levels are often elevated in females with PCOS as well. Insulin resistance with hyperinsulinism is seen in many patients with PCOS, more commonly when the patient is obese. Because PCOS is associated with metabolic syndrome, affected females should be screened for glucose abnormalities. Appropriate evaluations could include a hemoglobin A1c, fasting glucose, and a 2-hour oral glucose tolerance test, along with fasting lipid panel and complete metabolic profile. The increased risk of obstructive sleep apnea in women with PCOS has been attributed to hyperandrogenism, rather than to obesity alone.

**IDIOPATHIC HIRSUTISM.** Idiopathic hirsutism is a diagnosis of exclusion, defined as hirsutism with regular ovulation and normal androgen levels. Many mechanisms have been implicated, including minor ovarian or adrenal functional hyperandrogenism, increased peripheral conversion of testosterone to DHT, or abnormalities in the androgen receptor leading to increased sensitivity of hair follicles to normal androgen levels. A careful history, including a complete menstrual history as well as details of the onset and progression of the hair growth, and physical examination are important to exclude other diagnoses. Of note, menstrual regularity does not preclude an anovulatory state. Thus it is recommended to obtain an early-morning free testosterone level in the following patients: women with moderate or severe hirsutism, women with hirsutism of any degree with sudden onset or rapid progression, or women with accompanying signs or symptoms suggesting malignancy or PCOS.

**Figure 164-2** Modified Ferriman-Gallwey (F-G) hirsutism scoring system. The F-G score should be used during clinical examination of a woman with hirsutism. (Reprinted with permission from Yildiz BO, Bolour S, Woods K, Moore A, Azziz R. Visually scoring hirsutism. *Hum Reprod Update*. 2009;16[1]:51–64.)

### Treatment

Treatment options for hirsutism can be divided into pharmacological therapy and cosmetic management. Education about reasonable expectations is crucial: the effects of pharmacological therapy do not become evident before 6 to 12 months of treatment because of the long duration of the anagen phase of the hair cycle. The choice of treatment depends on patient preference, the extent to which the area of hirsutism is amenable to cosmetic hair removal, and cost of treatment.

In PCOS, there are 4 levels of treatment: restoration of menstrual regularity; treatment of hirsutism, which is typically the most distressing symptom of androgen excess in adolescents; treatment of obesity and metabolic abnormalities if they exist; and improvement of psychological impairment that may be associated with any of the above.

The first line of pharmacological treatment for both idiopathic hirsutism and hirsutism in PCOS is oral contraceptive pills (OCPs), which inhibit ovarian androgen biosynthesis in 2 ways: suppression of gonadotropin secretion and increased hepatic SHBG production (thereby decreasing free androgen concentrations). OCPs usually combine a synthetic estrogen and progestin. Products that contain low-androgenic progestins, such as drospirenone or norgestimate, should be used. In addition to decreasing hirsutism, OCPs regulate menstrual cycles and protect the endometrium which is beneficial in PCOS. Side effects include breast tenderness, gastrointestinal discomfort, and worsening of headaches in a patient with migraines. The most

serious side effect is the risk of venous thromboembolism, which is increased in women older than 35, with a history of cigarette smoking, and with a personal or family history of a clotting disorder. A careful assessment of these risks is warranted. Drospirenone has been implicated in imparting an even higher risk of thromboembolism than other progestins, but it is not clear if that risk is clinically significant. The long-term effect of OCPs on metabolic risks (lipid abnormalities and glucose tolerance) have not been closely studied, and should be kept in mind when choosing a regimen.

If hirsutism persists after 6 months of treatment with an OCP, or if the use of an OCP is contraindicated or not desired, an antiandrogen can be used. In women of child-bearing potential, antiandrogen medications should not be used without adequate birth control measures because feminization of the male fetus can theoretically occur. Spironolactone, the most widely prescribed antiandrogen, is also an aldosterone antagonist and so should not be used in patients with renal failure, hyperkalemia or in conjunction with other medications that cause hyperkalemia. Spironolactone is a competitive inhibitor of the androgen receptor and also inhibits 5 $\alpha$ -reductase activity, thus demonstrating properties of both flutamide and finasteride, other antiandrogens which have been used in the treatment of hirsutism. A study comparing these 3 agents demonstrated similar efficacies in the treatment of hirsutism after 6 months. The long-term use of pharmacological therapy for hirsutism in adolescent females has not been studied.

Cosmetic forms of hair removal include both temporary and permanent methods. Temporary treatments include hair removal from the skin surface (depilation) and those that extract hairs from above the bulb (epilation). Depilation methods include shaving and the use of chemical depilatory agents. Shaving is the least expensive method. Contrary to common belief, shaving does not increase the diameter of the hair follicle or affect the rate of hair growth; however, shaving can cause irritation and folliculitis. Depilatory agents dissolve hair by reducing the disulfide bonds and peptides of hair keratin at the skin surface. They can cause irritant dermatitis. Bleaching, although not a method of hair removal, can camouflage dark hair. Epilation methods include plucking and waxing. Plucking can be painful and time-consuming, making it useful only in small areas such as the face.

Electrolysis and photoepilation are methods of permanent hair reduction, not removal. Electrolysis involves placing a fine needle in the hair follicle and applying an electrical current. Because each follicle is treated individually, the process is time-consuming and difficult if large areas need treatment. Photoepilation uses lasers and other light sources such as IPL to damage hair follicles without damaging the surrounding tissues. It is most effective in patients with light skin complexion and dark hair. Although hair follicles are destroyed, vellus hair follicles can remain, and in patients with hyperandrogenism these follicles can convert to terminal hair resulting in hair regrowth. Photoepilation requires multiple treatments, is expensive, and can cause dyspigmentation and scarring.

Eflornithine hydrochloride cream, which has been approved for the treatment of facial hirsutism, irreversibly inhibits ornithine decarboxylase (ODC) in hair follicles. Essential in hair growth, ODC catalyzes the synthesis of polyamines, small cationic molecules that play a role in cell proliferation in hair follicle development and growth. The cream can be added to photoepilation therapy for a more rapid initial response.

In adolescents with PCOS who have abnormalities of glucose or significant hyperinsulinism, treatment should be aimed at managing metabolic abnormalities in conjunction with the above measures. Dietary and exercise changes should be the first-line treatment for obesity and dyslipidemia. Although these measures can be extremely challenging, it should be emphasized to the patient that as little as a 5% to 10% weight loss can have significant clinical outcomes, including improvement in biochemical hyperandrogenism, menstrual regularity, and glycemic profiles. Lifestyle changes with small achievable goals should be set. The current evidence suggests that multiple dietary strategies can be successful as long as they are nutritionally adequate and can be sustained. Goals for exercise should focus on overall health improvement, not weight loss.

Glucophage, a biguanide insulin sensitizing agent, is the single oral antihyperglycemic drug approved for use in children as young as 10 years of age. It inhibits hepatic glucose production and increases insulin sensitivity in peripheral tissues. The common side effects of nausea and diarrhea can be minimized by starting

at a low dose, titrating upward as tolerated, and taking it with meals. Long-term treatment with glucophage has been associated with malabsorption of B<sub>12</sub>. The most serious, although rare, complication is lactic acidosis. Glucophage is contraindicated with renal or hepatic impairment, severe congestive heart failure, or a history of alcohol abuse. It is used along with OCPs in the treatment of PCOS, especially in patients with diabetes or impaired glucose tolerance. In patients in whom OCPs are contraindicated or not desired, glucophage has been used as monotherapy.

Although the treatment of infertility is not a common issue in adolescence, the implication of PCOS on future fertility should be discussed with affected young women. At the time when fertility is desired, referral to a reproductive endocrinologist is appropriate.

## SUMMARY

Abnormal or excessive hair development is a common presenting complaint in the pediatric population. A thorough history and physical examination will guide further evaluation and separate benign conditions from more serious pathology. Premature adrenarche and PCOS may be manifestations of the same disease process, which may have origins in fetal life.

### WHEN TO REFER

- Signs of adrenarche (pubic hair, axillary hair, and/or odor) prior to age 8 in girls and 9 in boys
- Signs of virilization (clitoromegaly, masculine body habitus) in girls at any age
- Signs of virilization (penile enlargement, deepening of the voice) in boys prior to age 9 or rapid virilization at any age
- Signs of puberty in girls (breast development, menarche) prior to age 8
- Signs of puberty in boys (testicular enlargement) prior to age 9
- Symptoms of PCOS (hirsutism, menstrual irregularities) in girls
- Metabolic syndrome (obesity, hypertension, insulin resistance or type 2 diabetes mellitus, dyslipidemia)

### WHEN TO ADMIT

- Hypertension secondary to suspected mineralocorticoid excess (congenital adrenal tumor [CAH]–C-11 hydroxylase deficiency)
- Central nervous system (CNS) symptoms (headaches, visual changes) secondary to CNS lesions
- Severe abdominal and/or pelvic pain secondary to suspected mass
- Marked hyperglycemia requiring insulin treatment

## Chapter 165 HOARSENESS

Sanjay R. Parikh, MD

### DEFINITIONS

Normal voice production requires the ability to generate subglottic air pressure during expiration, adduction of the vocal folds (previously called cords), reliable vocal fold mucosal wave production, and exit of air through the upper airway. Hoarseness is a symptom of vocal dysfunction that describes a breathy, harsh, coarse, strained, or raspy voice. In children, hoarseness can be used to describe both the quality of the voice and the quality of the cry. Causes vary by age group and can be attributed to infectious, anatomic, traumatic, inflammatory, neoplastic, neurologic, and iatrogenic sources. The prevalence of childhood hoarseness has been estimated as 6% to 7%. Hoarseness and stridor may occur distinctly or sometimes concurrently. Hoarseness should be discerned from stridor, which is a sign of turbulent airflow caused by obstructive lesions within the upper airway. See Chapter 197, Stridor, for a detailed discussion.

### DIFFERENTIAL DIAGNOSIS

Forming a differential diagnosis (Box 165-1, Box 165-2) for the hoarse child depends on the quality of hoarseness, progression of symptoms, related infection, history of surgery or trauma, and associated respiratory distress. The age of the patient at the onset of hoarseness is a useful way to organize the potential causes.

#### Neonate and Infant

Hoarseness that occurs at birth or shortly thereafter is most often attributable to congenital, traumatic or iatrogenic, neoplastic, or inflammatory sources. In this subgroup of prelingual patients, hoarseness often refers to a weak or breathy cry.

Vocal fold paralysis in the neonate is a well-known cause of hoarseness and stridor. Bilateral vocal fold paralysis, which is usually congenital, often causes respiratory distress and stridor, whereas unilateral vocal fold paralysis is more likely to exhibit initially as hoarseness or dysphagia. Central nervous system (CNS) disease such as the Arnold-Chiari malformation must be ruled out in cases of bilateral vocal fold paralysis. A weak or breathy cry in a neonate after thoracic or cervical surgery should alert the physician to the possibility of recurrent laryngeal nerve injury as a source of iatrogenic vocal fold paralysis. Additionally, traumatic intubation can cause arytenoid cartilage dislocation, with subsequent vocal fold immobility and hoarseness.

Congenital laryngeal webs form as a result of failure of the larynx to canalize fully during embryologic development. Webs may occur exclusively with hoarseness, but they may be associated with aphonia, stridor, and respiratory distress. Laryngeal webs vary from thin slips of tissue between the anterior areas of the vocal folds to complete laryngeal atresia, which is incompatible with life unless recognized immediately. Atresia or near-total atresia has been referred to as congenital high airway obstruction syndrome. Laryngeal saccular cysts are characterized by symptoms of airway obstruction and dysphagia. Saccular cysts are filled with mucinous fluid and arise as a result of an abnormal dilation of the saccule of the larynx secondary to secretory outflow obstruction.

Posterior laryngeal clefts are an uncommon laryngeal anomaly that result in an abnormal opening in the posterior larynx. Clefts can simply involve the posterior laryngeal commissure, but may extend through the cricoid inferiorly through the tracheoesophageal septum. Symptoms depend on the extent of the cleft; at birth, clefts typically cause aspiration, stridor, respiratory distress, and weak cry.

Subglottic hemangiomas classically occur between the first and sixth month of life, with varying degrees of respiratory distress, stridor, cough, dysphagia, and hoarseness. The natural history of hemangiomas is that of proliferation followed by involution. Subglottic hemangiomas can be unilateral, bilateral, or circumferential, and are more common in girls than in boys. Cutaneous hemangiomas of the head and neck are found concurrently in approximately 50% of cases of subglottic hemangioma.

A relationship may exist between pediatric and adult laryngeal disease and reflux. Whereas

**BOX 165-1 Differential Diagnosis of Pediatric Hoarseness by Category****CONGENITAL**

- Laryngeal anomalies
  - Laryngomalacia
  - Glottic webs
  - Subglottic stenosis
  - Laryngeal cleft
- Cystic lesions
  - Laryngocele
  - Saccular cyst
  - Thyroglossal duct cyst
  - Cervical bronchogenic cyst
- Angiomas
  - Lymphatic malformation
  - Hemangioma
  - Arteriovenous malformation
- Cri du chat syndrome

**NEUROGENIC (CONGENITAL AND ACQUIRED)**

- Supranuclear (eg, hydrocephalus)
- Nuclear (Arnold-Chiari malformation, Guillain-Barré syndrome)
- Peripheral (eg, myasthenia gravis, cardiovascular anomalies, recurrent laryngeal nerve trauma)
- Psychogenic hoarseness

**VOCAL FOLD ABUSE**

- Vocal fold nodules
- Vocal fold polyps

**NEOPLASIA**

- Papilloma
- Squamous cell carcinoma

**PHYSICAL VOICE CHANGE OF PUBERTY****INFLAMMATORY**

- Infectious
  - Viral laryngopharyngitis (upper respiratory tract infection)

- Viral laryngotracheitis (croup)
- Bacterial supraglottitis (epiglottitis)
- Rare infections: (*Candida*, diphtheria, tuberculosis, leprosy)
- Noninfectious
  - Laryngopharyngeal reflux
  - Allergic laryngitis
  - Foreign body
  - Angioedema
  - Rheumatoid arthritis
  - Relapsing polychondritis
  - Chemical irritation (smoking, second-hand smoke, toxic fumes, inhaled medications)

**TRAUMATIC**

- Hematoma
- Laryngeal cartilage fracture
- Impacted foreign body
- Postintubation
  - Arytenoid dislocation
  - Fold avulsion
  - Granuloma
  - Acquired glottic web
  - Subglottic stenosis
- Recurrent laryngeal nerve injury
  - Thyroidectomy
  - Tracheotomy
  - Cardiac surgery
  - Tracheoesophageal fistula repair
  - Tracheal resection
  - Penetrating neck wound

gastroesophageal reflux (GER) refers to the backflow of stomach contents into the esophagus, laryngopharyngeal reflux (LPR) refers to the backflow of stomach contents into the throat, or laryngopharynx. Gastroesophageal reflux disease commonly produces emesis, dysphagia, sleep disturbance, and failure to thrive. The association among GER, LPR, and various neonatal laryngeal disorders such as hoarseness, posterior laryngitis, and silent aspiration, however, is an area of intense study that remains complicated and controversial.

**Older Child**

Older children and adolescents are subject to many of the same sources of hoarseness as adults. Infectious,

inflammatory, traumatic, and neoplastic conditions such as laryngitis, LPR, vocal nodules, and respiratory papillomata are the leading causes of hoarseness among older children.

Hoarseness of childhood from infectious disorders such as infective laryngitis, supraglottitis, and laryngotracheobronchitis rarely present a diagnostic challenge; however, concern over the airway should always take precedence. For example, hoarse voice may be an early indicator of the impending airway compromise seen in epiglottitis.

Although debate continues as to the specific role of LPR in the development of laryngeal lesions and hoarseness in children, infrequent reflux events have

### BOX 165-2 Differential Diagnosis of Pediatric Hoarseness by Age

#### 0 TO 6 MONTHS

- Traumatic intubation
- Iatrogenic: surgical
- Neurogenic: central or peripheral
- Neoplastic: hemangioma
- Congenital: web, cleft, cyst

#### 6 MONTHS TO 5 YEARS

- Traumatic: foreign bodies, intubation
- Infectious: URI
- Neoplastic: papillomas
- Behavioral, traumatic: nodules
- Inflammatory: allergy, LPR

#### 5 TO 13 YEARS

- Behavioral, traumatic: nodules
- Infectious: URI

- Neoplastic

#### 13 TO 18 YEARS

- Infectious: URI
- Inflammatory: allergy, LPR
- Behavioral, traumatic:
  - Male: mutational or transitional voice
  - Female: nodules
- Functional: muscle tension dysphonia

LPR, laryngopharyngeal reflux; URI, upper respiratory infection. Adapted and modified with permission from Smith ME, Gray SD. Voice. In: Bluestone CD, Stool SE, Kenna MA, eds. *Pediatric Otolaryngology*. 4th ed. Philadelphia, with permission PA: WB Saunders; 2003.

been shown to cause hoarseness in adults. LPR has also been found in association with pediatric laryngeal manifestations such as vocal fold nodules, posterior laryngitis, false vocal fold edema, vocal fold granulomas, functional voice disorders, and hoarseness. In addition, animal studies have shown that subglottic stenosis results when gastric acid is applied to the subglottic mucosa of dogs.

Vocal nodules arise from phonotrauma or voice abuse and are more common in boys than in girls. Symptoms may fluctuate based on aggravation by vocal abuse and respiratory tract infections. Sudden worsening of symptoms is sometimes seen when polyps swell from internal hemorrhage with excessive vocal trauma. Children with vocal nodules may share symptoms with other members of the immediate family who have similar vocal traits.

Airway trauma is also a potential cause of hoarseness in the older child and adolescent. Sources include blunt or penetrating injuries and intubation trauma.

Hoarseness of a progressive and unrelenting nature suggests a possible neoplastic cause. Ninety-eight

percent of pediatric laryngeal neoplasms are benign, and recurrent respiratory papillomatosis (RRP) is by far the most common lesion. RRP may be found on upper aerodigestive tract mucosal surfaces other than that of the larynx and have a characteristic cluster-of-grapes appearance. RRP may, however, be indistinguishable from the rare but ominous laryngeal squamous cell carcinoma of childhood.

Hoarseness in the adolescent years may also be of behavioral or psychogenic etiology. Mutational voice disorder occurs in male adolescents and results in hoarseness and high pitch during the stress of physiologic pubertal voice change. Paradoxical vocal fold dysfunction (seen more often in girls) is a disorder of psychogenic origin often misdiagnosed as asthma, which can produce episodic stridor or hoarseness.

## EVALUATION

### Relevant History

A thorough history is an essential part of the investigation of hoarseness. The age of the child is a critical factor in the development of an appropriate differential diagnosis, as is information on the quality of the voice with speech or crying, exacerbating or alleviating factors, and associated symptoms. Neurologic and congenital fixed anatomic lesions typically occur at birth, whereas inflammatory, neoplastic, traumatic, or iatrogenic causes of hoarseness occur later. The onset and course of dysphonia should be considered. Intermittent dysphonia may be related to infectious or inflammatory causes such as laryngitis, whereas persistent dysphonia may suggest a fixed anatomic lesion. A progressive, unremitting hoarse voice may suggest an enlarging neoplasm.

A review of medical and surgical history is also helpful. Patients with hoarseness who have symptoms such as regurgitation or vomiting, feeding difficulties, throat clearing, foreign body sensation, and cough may have underlying reflux.

Stridor that accompanies hoarseness should be investigated and treated expeditiously, because turbulent airflow resulting from airway obstruction may be life threatening.

### Physical Examination

A thorough physical examination, including a complete head and neck examination, should be part of the evaluation of pediatric hoarseness. Inspection of cranial nerve function and for craniofacial anomalies may reveal the underlying cause of a patient's hoarseness. Cutaneous head and neck hemangiomas, for example, may suggest a potential laryngeal hemangioma. Signs of aspiration during deglutition may be suggestive of sensorimotor causes of dysphonia such as vocal fold paralysis.

### Laryngoscopy

An essential part of the otolaryngologic physical examination is visualization of the larynx. Flexible nasopharyngolaryngoscopy, indirect mirror laryngoscopy, and rigid videostroboscopy are all methods for visualizing

the larynx that can provide useful, if not diagnostic, clues as to the source of a patient's hoarseness.

Indirect laryngoscopy using a mirror can be performed on cooperative children and can allow the physician to visualize gross disease and inflammatory changes in the larynx. This technique has largely been replaced by flexible fiberoptic nasopharyngolaryngoscopy, which provides clear views of laryngeal anatomy and function. Flexible endoscopy can be performed on virtually all age groups, although toddlers and patients who are developmentally delayed pose the greatest challenge to the examiner. Topical anesthesia can be used with topical decongestants to facilitate the examination. The flexible endoscope is gently passed through the nose or mouth. Examination in a nonmonitored setting, however, is not advisable if the patient has a tenuous airway or severe congenital cardiac anomalies.

Videostroboscopy uses a rigid, angled telescope placed gently into the oropharynx for dynamic examination of laryngeal anatomy and function. Examination requires a cooperative child. Videostroboscopy uses rapidly pulsed light to examine the vibratory characteristics of the vocal fold mucosa. Examinations are recorded on video to allow for repeated assessments viewed at different speeds to enhance visualization of the vibratory quality of the laryngeal mucosa. Vocal nodules or other lesions on the surface of the vocal fold will dampen the mucosal wave.

### Imaging

The role of diagnostic imaging in the workup of the hoarse child is of prime importance when the physician suspects CNS disease, external compression, malignancy, or external trauma.

Chest and neck plain-film radiographs may demonstrate mediastinal masses, cardiovascular anomalies, or abnormalities in the air column, suggesting possible infectious or obstructive diseases.

Computed tomography and virtual bronchoscopy are excellent methods for specifically defining the caliber of the airway and for delineating the site and extent of pathologic changes in airway caliber. Indications for laryngeal or neck computed tomography include congenital cysts, solid neoplasms, and external trauma.

Magnetic resonance imaging is helpful when suspicion exists of CNS disease such as the Arnold-Chiari malformation, and when evaluating possible airway hemangiomas or vascular malformations.

### Reflux Testing

Symptomatic or overt GER and LPR in the hoarse child may not necessitate expensive or invasive diagnostic studies. In the absence of identifiable disease in the hoarse child, however, investigation into LPR may be warranted. Although consensus on the role of LPR as it relates to various otolaryngologic manifestations is lacking, at least 1 study has used pH monitoring to suggest an association between pediatric reflux and hoarse voice in a cohort of children. Several diagnostic modalities exist for the workup of LPR, including pH monitoring, impedance testing, nuclear medicine

scintiscan, barium esophagoscopy, and direct laryngoscopy with or without biopsy.

Ambulatory 24-hour single-electrode pH monitoring remains the gold standard for the diagnosis of GER in infants and children. The double-electrode pH probe, with distal esophageal and pharyngeal electrodes, however, is thought to be the best method for diagnosing LPR and the otolaryngologic manifestations of GER.

Although pH-monitoring studies remain the gold standard for diagnosis of GER and LPR, they do not detect episodes of nonacidic reflux. Multichannel intraluminal impedance monitoring and nuclear medicine scintigraphy can measure both acidic and nonacidic episodes of reflux, which may play a role in such serious events as apnea, apparent life-threatening events, aspiration, and sleep disturbance. Nuclear medicine scintiscans have specificity between 83% and 100%, but they have been shown to be only 15% to 59% sensitive and lack a standardized technique, limiting the usefulness of comparisons between studies. Impedance monitoring evaluates the pH-independent change in intraluminal electrical resistance that occurs with the movement (antegrade or retrograde) of a bolus of food, liquid, or gas within the esophagus. This technique may be a reliable tool for evaluating the association between GER-related symptoms and nonacidic reflux events, and it may ultimately replace pH monitoring as the standard tool for detecting LPR in infants and children.

Barium esophagram has variable sensitivity and specificity for the diagnosis of LPR. It is useful mainly for detecting anatomic abnormalities such as hiatal hernia.

Laryngoscopy with biopsy may be the most specific test for LPR, but at least 1 study has failed to show a correlation between laryngoscopy and upper pH probe findings with significant laryngeal histopathologic inflammatory findings.

## MANAGEMENT

### Congenital Lesions

Management of hoarse voice resulting from unilateral or bilateral vocal fold paralysis is usually secondary to stabilization of the airway and management of dysphagia and aspiration. Tracheotomy is sometimes required in patients with bilateral vocal fold paralysis, but conservative management in select patients has been advocated. However, patients with congenital or acquired unilateral vocal fold paralysis often recover normal vocal quality by spontaneous resolution of the paralysis or by compensatory movement of the unaffected fold over time. Recovery has been noted up to 11 years after paralysis. In cases of persistent unilateral fold paralysis with persistent hoarseness, the treatment of choice remains speech therapy, although reports have surfaced of successful surgical vocal fold medialization techniques in the children.

Laryngeal webs are managed surgically, either endoscopically or via more extensive open laryngotracheal reconstruction techniques. The type of operation

depends primarily on the location and extent of the lesion, with thin webs being more amenable to endoscopic management.

Saccular cysts of the larynx are often managed endoscopically with excellent results via aspiration and marsupialization by sharp dissection or with the carbon dioxide (CO<sub>2</sub>) laser. Cyst recurrence, however, is well documented following endoscopic management, and open resection of the cyst may be necessary in these cases.

Posterior laryngeal clefts vary greatly in their extent and symptoms. Extensive or symptomatic clefts must be repaired as early as possible. Although endoscopic repair is possible in small clefts limited to the larynx and upper trachea, more extensive open techniques are used for larger clefts. Tracheotomy may also be placed in cases in which staged reconstruction of the cleft is necessary, and a gastrostomy tube is often needed to limit aspiration and protect the operative site following surgical repair of the cleft.

### Neoplasia

Subglottic hemangioma is a complicated airway anomaly without a universally accepted treatment. Numerous management options exist, including close observation, systemic or intralesional steroids, laser ablation, open surgical excision, and tracheotomy.

Recurrent respiratory papillomatosis associated with human papilloma virus (HPV), represents another airway tumor with a large number of accepted primary and adjuvant therapeutic modalities. CO<sub>2</sub> laser excision was developed as a treatment for RRP in the 1970s and remains a popular method for removing laryngeal papilloma, although it is associated with potentially severe sequelae such as airway fire, scarring, chronic laryngeal edema with airway compromise, vocal fold scarring, and poor voice. Nonlaser therapies such as cold dissection and powered débridement have also been used successfully for excision of RRP with comparable outcomes. Several adjuvant therapies, such as intralesional cidofovir,  $\alpha$ -interferon, indole-3-carbinol, bevacizumab, and heat-shock protein E7, have been used with varying degrees of efficacy and safety. There is hope that with the introduction of HPV vaccines there may be a future generational shift in the reduction of RRP.

### Inflammation and Infection

Behavioral and lifestyle modifications; pharmacotherapy using H<sub>2</sub> antagonists, proton-pump inhibitors, prokinetic agents, and antacids; and surgical therapy with fundoplication are acceptable for the management of GER and LPR in infants and children.

Viral laryngitis and laryngotracheobronchitis are generally treated conservatively, but they may require airway protection or intravenous steroids in severe cases. Bacterial infections such as epiglottitis and membranous laryngotracheobronchitis, though now rare, necessitate early airway protection and intravenous antibiotics directed against *Staphylococcus aureus* and *Haemophilus influenzae*, unless culture results direct differently.

### Trauma

The management of vocal fold nodules resulting from phonotrauma primarily relies on behavioral modification and speech therapy aimed at maximizing vocal hygiene. Only in rare circumstances is surgical excision indicated, because failure to correct the underlying voice misuse is likely to result in nodule recurrence.

Arytenoid dislocation resulting from intubation trauma can be adequately treated if recognized and reduced early under anesthesia with microlaryngoscopy.

Blunt laryngeal trauma resulting in hoarseness necessitates close observation and may require the use of systemic corticosteroids and tracheotomy in cases of severe laryngeal injury and edema. In adolescents with laryngeal fracture, open reduction and fixation may be required.

For patients with hoarseness related to iatrogenic unilateral vocal fold immobility, injection or external vocal fold medialization have been showed to be effective. Recurrent laryngeal nerve reinnervation procedures are also emerging as promising therapeutic options for long-term improvement.

## SUMMARY

Most cases of pediatric hoarseness result from benign, reversible, and self-limited disease; however, some causes of hoarseness are progressive, malignant, and potentially life-threatening. Thorough evaluation, precise diagnosis, and appropriate intervention are therefore essential.

### WHEN TO REFER

- Recognized cardiac, esophageal, or neurologic disease
- Progressive hoarseness
- Presence of cutaneous hemangioma
- Hoarseness after external trauma or uneventful intubation
- Poor speech intelligibility or psychosocial sequelae
- Hoarseness that has been present since birth

### WHEN TO ADMIT

- Presence of respiratory distress, stridor, tachypnea, or tachycardia
- Hoarseness following external trauma

## Chapter 166 HYPERHIDROSIS

Nancy K. Barnett, MD

When excessive (beyond the norm for thermoregulation) localized sweating occurs in childhood, the child or the family usually expresses concern because the sweating is either odiferous or so intense that it interferes with hand functions (eg, holding a pencil) or foot functions. Axillary hyperhidrosis usually becomes more of a problem in adolescence because of the embarrassment of the sweat ring on clothing and the odor associated with bacterial degradation of apocrine sweat. The apocrine glands are stimulated at puberty by androgenic hormones. Palmar and plantar hyperhidrosis caused by eccrine sweat production may occur at any age. Eccrine sweat glands controlling thermoregulation are most numerous on the palms, soles, and axillae.

Palmoplantar hyperhidrosis is thought to be stimulated by anxiety, whereas axillary hyperhidrosis is probably stimulated by both heat and emotion. Both stop during sleep. Researchers have postulated that emotions and the temperature of the blood perfusing the hypothalamus stimulate the secretion of the hormones that regulate the autonomic nervous system's control of perspiration such that cholinergic sympathetic fibers hyperstimulate eccrine and apoeccrine sweat glands.

## EVALUATION

Excessive sweating that is not limited to the palms, soles, and axillae may be caused by and indicate a systemic disorder, such as infection, hypoglycemia, drug withdrawal, lymphoma, thyrotoxicosis, pheochromocytoma, or Riley-Day syndrome. These disorders should be considered in the presence of generalized increased perspiring.

## MANAGEMENT

Systemic anticholinergic agents may block acetylcholine, the sympathetic innervation terminal neurotransmitter to eccrine glands, and help hyperhidrosis, but the side effects of cholinergic blockage preclude their long-term use. The application of prescription 20% aluminum chloride (eg, Drysol) every other day has been an effective treatment for palmar sweating. Plantar hyperhidrosis also responds to aluminum salts, and absorbent powders (eg, Zeasorb) are used more

easily here than on the palms. Some authors report successful control of palmar and plantar hyperhidrosis with tap-water iontophoresis.

Palmar and plantar hyperhidrosis can be controlled by inhibiting sweat production with subepidermal injections of botulinum A toxin, which purportedly blocks the presynaptic acetylcholine release and is effective for as long as 12 months. Patients as young as 14 years have been treated in this manner, but temporary or, rarely, permanent muscle and nerve injury from the injections limits the toxin's usefulness in these locations.

For bromhidrosis (malodorous hyperhidrosis) of the soles, cleansing frequently with drying deodorant soaps and applying topical antibiotics (erythromycin or clindamycin) may help. The patient should go barefoot whenever possible.

Axillary hyperhidrosis is troublesome because continual sweating makes maintaining an effective antiperspirant in contact with the axillary skin difficult. One approach is to apply prescription 20% solution of aluminum chloride in anhydrous ethanol to the axillary vault. A problematic side effect of this treatment can be an irritant contact dermatitis, uncomfortable enough to require hydrocortisone cream for relief of inflammation. For individuals who have axillary hyperhidrosis and bromhidrosis, frequent clothing changes may be necessary, as may the use of topical antibiotics and deodorant powders. Propranolol and anxiolytics are options to reduce emotional stress.

Successful axillary sweat gland chemodenervation with intradermal botulinum toxin injections is being increasingly used and is an approved indication for the toxin. In extreme cases, when these measures fail and the patient is desperate for relief, local axillary skin can be excised or glands removed by less scarring curettage or liposuction techniques with reasonable expectation of success. Because of its attendant complications, ganglion sympathectomy cannot be recommended for most patients who have axillary hyperhidrosis. Hyperhidrosis is often life altering, and data exist to support management, even with significant measures like axillary suction curettage, because it improves quality of life.

Management of primary palmoplantar and axillary hyperhidrosis may have the secondary benefit of decreasing the significant risk for associated infections such as warts, dermatophytosis, and pitted keratolysis as well as eczematous dermatitis, which can coexist.

## WHEN TO REFER

- Hyperhidrosis that interferes with the function of a body part (eg, hand so slippery wet that the child cannot hold a pencil)
- Generalized excessive sweating
- Socially isolating hyperhidrosis as a result of odor or excessive drenching of clothing

## Chapter 167

# HYPOTONIA

Alfred J. Spiro, MD

Hypotonia indicates diminished resistance to passive movement around the range of motion of a joint. The commonly used term *floppy* refers to hypotonia, or weakness, or both. No readily administered, accurate test exists to quantify hypotonicity. Furthermore, tone, especially in a young infant, may vary greatly during the day or even during the examination. Hypotonia is not a diagnosis in itself; however, the origin of a neonate's floppiness may be obvious in, for example, overwhelming sepsis, meningitis, or marked hyperbilirubinemia. Central nervous system (CNS) abnormalities are commonly associated with hypotonia. Generally, central hypotonia involves diminished tone without appreciably diminished strength coupled with preserved or hyperactive deep tendon reflexes. In disorders of the motor unit (lesions of the anterior horn cell, peripheral nerve, myoneural junction, or muscle), strength is usually diminished, and tone may be reduced as a result. Hypotonia that is not associated with a motor unit disorder is more common than hypotonia caused by an underlying motor unit disorder. Testing of strength in infants and young children is difficult, even for experienced examiners; it can usually be done by observation of how strong a baby's kicking and pushing are, for example, or by functional testing.

## HYPOTONIA NOT CAUSED BY MOTOR UNIT DISORDERS

Disorders virtually anywhere in the brain may be associated with hypotonia. Global developmental delay is a common, but not universal, accompanying feature, as is microcephaly. Magnetic resonance imaging (MRI) of the brain may be helpful in documenting the lesion in some cases. In many instances, a specific diagnosis cannot be made. As infants who have hypotonicity get older, the abnormal tone may evolve into spasticity and the diagnosis of spastic quadriplegia, spastic diplegia, or other form of cerebral palsy becomes evident. A common misconception is that cerebral palsy is caused by obstetrical trauma; in most instances, the cause of cerebral palsy remains unknown. Nevertheless, a review of birth records, drug administration, and factors surrounding prematurity is indicated. On examination, deep-tendon reflexes are usually but not always hyperactive. Abnormalities of tone in patients with cerebral palsy are usually global; that is, both proximal and distal. Treatment of various types of cerebral palsy is supportive and symptomatic and usually requires a multidisciplinary team effort.

Several genetic syndromes, Down syndrome among the most common, are associated with hypotonia; the diagnosis can be made on clinical grounds and with appropriate genetic studies. Newborns and young infants with Prader-Willi syndrome may be extremely hypotonic and demonstrate a diminished level of consciousness. As these babies get older, tone may

improve, and they may become obese. They have characteristic almond-shaped eyes, short stature, and some degree of intellectual disability and hypogonadism; some have severe eating disorders and scoliosis, but these features are usually not present until school age. The clinical features coupled with analysis showing a deletion in the chromosome 15q11-13 region can generally establish the diagnosis.

Several of the Ehlers-Danlos syndromes may simulate hypotonicity, but the major feature of this group of connective tissue disorders is hyperlaxity of joints. Weakness is not a prominent feature.

Hypothyroidism and other metabolic disorders may be accompanied by hypotonia. Neonatal screening generally includes a test for hypothyroidism. If the diagnosis is not obvious on physical examination, then appropriate thyroid function studies can be done.

## HYPOTONIA CAUSED BY MOTOR UNIT DISORDERS

### History

In taking the history, the primary care physician should note whether hypotonia was present at birth or was recognized later. Parents of first children may have no basis for comparison and may not recognize an abnormality. Occasionally, photographs or family videos can be extremely useful in revealing abnormalities denied or not noted by parents. Breech presentation is common in babies who are subsequently diagnosed as having a motor unit disorder, but the reason for this has not been established. Congenital hip dislocation may be present in children who have central core disease, a congenital myopathy.

Thorough questioning can usually determine whether the hypotonia is improving or worsening or if weakness is periodic, as observed in hyperkalemic periodic paralysis (a rare autosomal-dominant disorder with onset usually in infancy or early childhood). The distribution of weakness, whether it is predominantly proximal, distal, or global, can also be identified with questions such as whether the baby or child moves the fingers and toes better than the large muscles of the pelvic and shoulder girdles. Details of the child's developmental milestones also can provide a clue to the nature of the lesion. For example, language development is normal in infantile progressive spinal muscular atrophy (SMA) and impaired in myotonic dystrophy.

Facial muscle weakness, observed in some congenital myopathies, can be considered if the parents state that the child sleeps with the eyelids partially open. Extraocular muscles, in addition to facial muscles, are abnormal in myotubular myopathy. Acquired autoimmune myasthenia gravis and myasthenic syndromes can occur in young children and may cause ptosis, extraocular muscle weakness, and, in some cases, generalized weakness and respiratory distress. Less severely affected patients may have only limited abnormal findings at the time of examination. Family videos taken at the times of the patient's maximal clinical involvement can be useful to document signs not seen in the examining room. Physicians should inquire about swallowing and sucking difficulties.

Details of the family history can be helpful because many of the motor unit disorders are genetic. The

presence of consanguinity suggests an autosomal-recessive entity. Examining parents and siblings can sometimes be revealing because some genetic disorders may be expressed quite subtly in family members and often are overlooked. Facial muscle weakness is a common example; patients do not seek medical attention if they cannot puff up their cheeks, whistle, or squeeze their eyelids closed completely, all features seen in certain congenital myopathies or facioscapulo-humeral muscular dystrophy. If early-onset myotonic dystrophy type 1 is thought to exist, then the child's mother and other family members should be examined for myotonia (slowed relaxation after a voluntary or induced muscle contraction) because neither percussion nor electrical myotonia is observed in infants or very young children.

### Physical Examination

The physician should conduct a thorough search for systemic disorders. Dysmorphic features such as high-arched palate and dental malocclusion are observed in some congenital myopathies, such as nemaline myopathy. An enlarged heart and congestive heart failure are observed in glycogen storage disease caused by acid maltase deficiency. Clubfoot deformity is commonly seen in the infantile form of myotonic dystrophy. Joint abnormalities and scoliosis are common in several motor unit disorders.

A striking paucity of spontaneous movement is observed in infantile progressive SMA; paradoxical respiration, in which the chest wall moves inward during inspiration instead of expanding, is also observed often.

In infants and in children younger than 5 years, manual muscle testing generally cannot be accomplished reliably, making observation of spontaneous movement and functional testing, such as the ability to hold the head erect, sit, roll over, and stand, and walk on heels and toes, mandatory. Assessing cranial nerve function should emphasize identifying facial and extraocular muscle weakness, as well as fasciculation and atrophy of the tongue. Fasciculation of the tongue, observed in infantile progressive SMA, should be assessed with the tongue not protruded and with the child not crying. Tremulousness of the outstretched fingers (minipolymyoclonus) is seen almost exclusively in SMA with a protracted course and in some hereditary sensorimotor neuropathies. Generally, deep-tendon reflexes are reduced or absent in motor unit disorders but preserved in most cases of myasthenia gravis. With hypotonia of central origin, reflexes are preserved or hyperactive; however, many exceptions to this rule can be found. The presence or absence of extensor plantar responses is also often difficult to assess in young children; these responses may normally be present at up to a year or more of age.

### Laboratory Studies

Laboratory studies include blood testing, neurophysiologic evaluation, and histologic examination of muscle. Laboratory studies should be goal directed and performed in an orderly manner. Serum muscle enzyme levels, particularly creatine kinase, are always markedly elevated in Duchenne and Becker muscular dystrophy but are not always increased in congenital myopathies. They are generally normal or only

minimally increased in spinal muscular atrophy. DNA studies for diagnostic purposes are readily available in many commercial and research laboratories (see Gene Tests or OMIM in the Tools for Practice section at the end of this chapter) for several motor unit disorders, including infantile progressive SMA, myotonic dystrophy, various hereditary sensorimotor neuropathies, selected mitochondrial myopathies, and Duchenne and Becker muscular dystrophy. When these disorders are thought to exist on clinical grounds, an appropriate DNA study may be all that is needed to document the diagnosis. Thus, a child who has classic infantile progressive SMA can be spared many painful studies when the DNA study is conclusive. Other noninvasive studies, such as computed tomography, MRI, or sonographic imaging of muscles, can assess muscle mass accurately; in the presence of very small muscles, imaging is indicated if a muscle biopsy is contemplated. Electromyographic studies can be useful in the diagnosis of motor unit disorders, but because of the pain involved and the need for sedation in some cases, they should be used with discretion when DNA studies are not helpful. Nerve conduction studies can be extremely useful in distinguishing the various types of peripheral neuropathies seen in infants and children. Repetitive stimulation studies are very helpful in diagnosing disorders of the myoneural junction, including infantile botulism, but testing can be quite painful. Physicians who are experienced in the particular technical and other problems encountered in this age group should perform all electrodiagnostic studies in young children.

Muscle biopsies, performed either with a special needle or surgically, are most useful in myopathies such as congenital myopathies, congenital muscular dystrophy, metabolic myopathies, and mitochondrial disorders. Many specialized analytical studies are available when needed. In virtually all instances when a biopsy is performed, sections should be taken for histochemical, biochemical, ultrastructural, and genetic studies, although not all of these studies are used in every case.

### Selected Motor Unit Disorders

#### *Anterior Horn Cell Disease*

Given the near elimination of paralytic poliomyelitis in the United States, the various types of infantile progressive SMA constitute the major disease in this category. Eponyms have been applied to these disorders, including Werdnig-Hoffmann disease, but these terms may be misleading and confusing. Now, a much more useful operational classification of SMA (Table 167-1) is commonly used.

In all types of infantile progressive SMA, cognition is normal, as are extraocular muscles. Weakness and muscle wasting are proximal more than distal and are more pronounced in the legs than in the arms. Fasciculation of the tongue and minipolymyoclonus (in types I and II, respectively) are observed often, and areflexia and normal sensation are the rule. Joint contractures and scoliosis may develop, especially in type II. All forms are autosomal recessive, with the responsible gene having been located at 5q11-q13. A deletion of the survival motor neuron gene has been identified in most patients, making this situation useful for diagnostic purposes and for prenatal diagnosis. Recent advances

**Table 167-1 Spinal Muscular Atrophy**

TYPE	AGE OF ONSET	COURSE
I	Birth to 6 mo	Never sits independently, even when placed; progressive; demise <2 y
II	6–18 mo	Sits independently when placed; life expectancy into the 20s or later
III	>18 mo	Weakness after having learned to walk; normal life expectancy

in understanding the molecular basis of this disorder have made phenotype-genotype correlation possible. Treatment generally is supportive and includes physical therapy and, when needed, respiratory and nutritional support and genetic counseling. Scoliosis is common in type II and must be addressed appropriately with a body jacket, molded back support, or surgery. Most children who have type II can use a motorized wheelchair at approximately 2 to 3 years of age. Life expectancy in type II can be well into adulthood.

### Peripheral Nerve Disorders

Peripheral nerve disorders are rare in infancy and very early childhood. Hypomyelinating neuropathy can produce severe weakness, hypotonia, and areflexia in a neonate or young infant. The diagnosis can be anticipated when extremely abnormal nerve conduction studies are encountered and can be confirmed with DNA studies or with a nerve biopsy. Hereditary sensorimotor neuropathies, with the many variants of Charcot-Marie-Tooth disease, are the most common cause of childhood peripheral nerve disorders and may cause both gait abnormalities from weakness of the anterior tibialis muscles and deformities of the foot. Ankle jerks are often diminished or absent, but all reflexes may be preserved in the early phases of peripheral neuropathies. Nerve conduction studies can be extremely useful in separating axonal from demyelinating neuropathies. DNA studies can be diagnostic in selected hereditary neuropathies, especially the demyelinating and the X-linked varieties. Treatment addresses symptoms; some children who have foot drop may require bracing.

Several CNS disorders may have a demyelinating form of peripheral nerve involvement in addition to abnormalities in the cerebral white matter; these include metachromatic leukodystrophy, Krabbe disease, and adrenoleukodystrophy.

### Myoneural Junction Disorders

Several disorders of the myoneural junction affect children and infants: passively acquired autoimmune myasthenia gravis, also known as transient neonatal myasthenia; acquired autoimmune myasthenia gravis, also known as juvenile or childhood myasthenia; nonautoimmune myasthenic syndromes, also known as congenital myasthenia gravis; and infantile botulism.

Passively acquired autoimmune myasthenia gravis occurs in approximately 20% of infants born to mothers who have myasthenia gravis. All newborns of seropositive mothers have acetylcholine receptor

antibodies, but only a small portion are symptomatic, most mildly, but some more severely, with hypotonia, a weak cry, swallowing and sucking difficulty, facial diaphoresis, respiratory distress, external ophthalmoparesis, and ptosis. The diagnosis can be made quickly when, after administering intravenous edrophonium, the abnormal findings subside. When the newborns are symptomatic, pyridostigmine can be given orally until symptoms are no longer present. The dose is then tapered, usually over a period of 1 to 2 weeks. These infants do not have clinical features of myasthenia gravis after the initial involvement. If weakness does not occur by 1 week of age, then it is highly unlikely to develop.

Major features of acquired autoimmune myasthenia include fatigability and fluctuating weakness of extraocular, facial, and lingual muscles, and, in some instances, mild or severe generalized weakness and hypotonicity of the limbs. An acute fulminating onset may be encountered in young children. The diagnosis can be made by using the edrophonium test and confirmed with the acetylcholine receptor antibody test, although the latter is not necessarily positive in milder cases and is less useful in children than in older individuals. Electrodiagnostic studies can be used in selected instances in children but are generally less useful than in adults. The mediastinum should be radiographed to assess thymic size, and thyroid function studies should be obtained to exclude associated hypo- or hyperthyroidism. Treatment includes judicious use of anticholinesterase drugs and, when needed, immunosuppressive treatment, intravenous gamma globulin, corticosteroids, and thymectomy.

Nonautoimmune myasthenic syndromes may be associated with ocular, bulbar, or respiratory involvement and, in some instances, with progressive weakness and hypotonicity. Some disorders may be genetic; patients are seronegative. Specialized electrodiagnostic and ultrastructural studies are required to establish an exact diagnosis, which is important in selecting appropriate therapy. For the moment, genetic studies for diagnosis are available only within a research setting. Some patients respond to anticholinesterase inhibitors or corticosteroids; others require diaminopyridine or other specific medications.

Infantile botulism is characterized by onset at an average age of slightly more than 3 months that produces weakness and hypotonia, poor feeding, constipation, and diminished activity. The onset may be rapid, developing over 2 to 3 days. The diagnosis is confirmed when the toxin is documented in the stool or when the organism is isolated from culture, but repetitive stimulation studies can be extremely useful in establishing the diagnosis quickly. Treatment is supportive; specific immune globulin may prove to be therapeutic.

### Myopathies

Myopathies constitute a diverse group of genetic, inflammatory, and metabolic disorders that involve muscle and, in many cases, other organ systems, including the brain and heart. Inflammatory myopathies (dermatomyositis) are seen only rarely in very young children and generally produce subacute weakness, not hypotonia. Patients with Duchenne muscular dystrophy (among the most common muscular disorders) do not have hypotonia in infancy. In the infantile form

of myotonic dystrophy–type 1 hypotonia can be severe at birth. Obtundation, difficulty with sucking and swallowing, weakness of facial muscles, clubfeet, and areflexia may be present. Myotonia will not be present either clinically or electrically until patients are older than 5 years. A neonate who survives will gain strength and tone and will eventually walk. Until strength and tone improve, assisted ventilation and gastrostomy tube feedings are often needed. Myotonic dystrophy–type 1 is an autosomal-dominant disorder; however, when it occurs in the neonatal period, it is virtually always the mother who transmitted the gene. She should be examined for the characteristic features of the disease, which include reflex and percussion myotonia, weakness of the neck flexor muscles, smallness of the sternocleidomastoid muscles, weakness of the wrist extensors and anterior tibialis muscles and facial muscles, and, often, intellectual disability. For children who first exhibit myotonic dystrophy beyond infancy, either parent may have transmitted the gene, which is located on 19q13. DNA studies can be done to document the diagnosis and predict the prognosis. This condition is an expanded trinucleotide repeat disorder, with correlation between the severity and the number of repeats. Family members should be provided with genetic counseling, given that prenatal diagnosis is available. Treatment is supportive.

Several congenital myopathies have been identified and are generally diagnosed on muscle biopsy by their characteristic morphologic mechanism. These myopathies, typified by nemaline myopathy, are often hereditary and are associated with varying degrees of hypotonia and weakness and sometimes with respiratory and sucking problems early in life. Some have rather characteristic clinical features. For example, in X-linked myotubular myopathy of very early onset, the extraocular and facial muscles are weak, in addition to generalized hypotonia and weakness. Central core disease is associated with congenital hip dislocation and a propensity for malignant hyperpyrexia. In some congenital myopathies, the gene location has been identified, but DNA testing is not yet available for establishing the diagnosis.

The congenital muscular dystrophies comprise a diverse group of diseases in which varying degrees of weakness and hypotonia are present early in life. Muscle biopsy shows characteristic, but not specific, pathologic findings, and more refined studies are required. The serum muscle enzymes (creatine kinase) are generally elevated, and, in some forms of this disorder, merosin is absent on the biopsy specimen. The merosin-deficient type of congenital muscular dystrophy is often associated with intellectual disability, seizures, and white matter brain abnormalities. In Japan, Fukuyama-type congenital muscular dystrophy is common and is also associated with severe CNS abnormalities.

Facioscapulohumeral muscular dystrophy usually occurs in older children but, at times, will produce severe facial weakness in early childhood. Although sometimes sporadic, most cases are autosomal-dominant and parents of affected children should be examined for involvement that may be very mild and go unnoticed, such as facial muscular weakness, scapular winging, and a round-shouldered stance. This

disease is genetically linked to high-frequency hearing deficits. Treatment is symptomatic, and it is appropriate to offer genetic counseling. DNA studies are available to document the diagnosis when this disorder is thought to exist, making electrodiagnostic testing and muscle biopsy unnecessary.

Glycogen storage disease caused by deficient acid maltase, in addition to its neuromuscular manifestations (hypotonia and weakness), is associated with a markedly enlarged heart and congestive heart failure. The diagnosis can be made readily by specific blood tests. Enzyme replacement therapy has recently become available; without this treatment, the prognosis is dismal. This condition is an autosomal-recessive disorder with the responsible gene located at 17q23.

An increasing number of mitochondrial encephalomyopathies are being reported that have varying CNS and muscle involvement. Lactic acidemia is common, but specialized genetic and other studies on muscle mitochondria are needed to provide a specific diagnosis if DNA studies are unrevealing. Treatment addresses symptoms.

Congenital hypotonia with favorable outcome or benign congenital hypotonia is a retrospective diagnosis used to denote infants who have hypotonia of early onset with a benign course. This relatively unclear disorder is often associated with joint hyperlaxity, sometimes also noted in parents or other relatives. In many instances, by 5 years of age, the children are indistinguishable from other children their age.

### WHEN TO REFER

- Persistent lack of normal motor development
- Regression of motor development
- Sudden or precipitous worsening of tone or strength
- Swallowing dysfunction
- New onset of neurologic signs

## Chapter 168

**INATTENTION AND IMPULSIVITY***Lawrence S. Wissow, MD, MPH***INTRODUCTION**

Symptoms of inattention and impulsivity affect many children, including a large number whose symptoms do not rise to the level of a disorder. Attention-deficit/hyperactivity disorder (ADHD) occurs in about 8% of children and youth, who experience significant impairment in their functioning as a result of their symptoms. As part of their condition, individuals with ADHD often have deficits in social skills, impairing their abilities to function well in school and social settings. ADHD is frequently comorbid with learning difficulties, and the 2 conditions can mimic each other in school or during cognitive tasks outside of school (including time devoted to doing homework). Thus, ADHD can result in significant adverse consequences. Follow-up studies have found that children with ADHD, particularly those untreated, are at greater risk for school failure, underemployment, difficulty with legal authorities, substance abuse, and morbidity from risky behaviors including motor vehicle crashes and sexually transmitted infections.

The guidance in this chapter applies to the care of children presenting with undifferentiated symptoms of inattention and impulsivity in pediatric clinical settings.

This chapter is based on the work of the World Health Organization, whose recommendations may be updated annually. The most up-to-date information can be found at [www.who.int](http://www.who.int).

**FINDINGS SUGGESTING INATTENTION AND IMPULSIVITY**

Inattention and impulsivity occur commonly during childhood. When these symptoms occur more persistently and to a greater degree than is seen in a child's peers, there may be cause for concern. Often, the child's teacher is the first to observe the symptoms or to encourage medical attention for them. A summary of the symptoms and clinical findings that suggest inattention and impulsivity can be found in Box 168-1. These symptoms may be elicited from parents, teachers, or youth. Because observers often disagree about behavioral and emotional symptoms, collecting information from all 3 sources can be helpful, and the process of reconciling differences can itself be therapeutic.

**TOOLS TO ASSIST WITH IDENTIFICATION**

Since many children do not spontaneously disclose their symptoms, standardized wide-range psychosocial screening instruments may be used to identify children with emotional and behavioral difficulties that may include symptoms of inattention and impulsivity. Diagnostic criteria for ADHD require presence of symptoms in more than 1 setting; therefore, collateral reports from the school or child care center, as well as the

**BOX 168-1 Indications in History From Youth or Parent**

- Excitability, impatience, angry outbursts (more than is seen in peers)
- Wandering attention (greater than is seen in peers)
- Difficulties with behavior at home and in the classroom
- Academic difficulties
- Parents and teachers presuming diagnosis of ADHD or seeking diagnosis of ADHD

parent(s), are critical elements in the identification process. Several instruments have versions to collect information from the youth, parents, and teachers. Table 168-1 provides an overview of general psychosocial screening tools available in the public domain, along with results raising concerns in the areas of inattention and impulsivity. Use of additional instruments, such as the Vanderbilt ADHD Rating Scales, can then help to confirm findings of the initial screening, corroborate a concern raised by a teacher or parent, and serve as a benchmark to track treatment progress. Use of a functional assessment tool such as the Impact Supplement of the Strengths and Difficulties Questionnaire (SDQ) or the Columbia Impairment Scale (CIS) will assist in determining whether the child is significantly impaired by the symptoms. Use of a tool to assess the effect of the child's problem on other members of the family may also be helpful; the Caregiver Strain Questionnaire (CGSQ) is an example of such a tool.

**ASSESSMENT**

Assessment begins by differentiating the child's symptoms from normal behavior. All children may be inattentive or impulsive at times, but, for some children, inattention and impulsivity limit their adaptability to normal peer and family situations and interfere with learning. Inattention and impulsivity are typical characteristics of preschool children, but extremes of these behaviors warrant further evaluation (eg, concern that the behavior is harming family or peer relationships, interfering with learning, or putting the child at risk for expulsion from child care or school because of behavior). Boisterousness or dreaminess can be normal behavior patterns in older children. Children with limited social experiences and those whose environment is relatively less structured may seem impulsive and inattentive compared to their peers, especially when entering highly structured situations such as a classroom or organized group activities.

Table 168-2 provides a summary of conditions, such as hearing or vision problems, receptive and expressive language problems, learning disorders, and sleep deprivation, which may mimic or co-occur with inattention and impulsivity problems.

**PLAN OF CARE FOR CHILDREN WITH INATTENTION AND IMPULSIVITY**

The care of a child experiencing symptoms of inattention and impulsivity can begin in the primary care

**Table 168-1** General Psychosocial Screening/Results Suggesting Inattention and Impulsivity

SCREENING INSTRUMENT	SCORE
Pediatric Symptom Checklist (PSC)-35	<ul style="list-style-type: none"> <li>• Total score <math>\geq 24</math> for children 5 years and younger.</li> <li>• <math>\geq 28</math> for those 6–16 years.</li> <li>• <math>\geq 30</math> for those 17 years and older.</li> </ul> AND <ul style="list-style-type: none"> <li>• Further discussion of items related to attention and impulse control confirms a concern in that area.</li> </ul>
PSC-17	<ul style="list-style-type: none"> <li>• Attention subscale is <math>\geq 7</math>.</li> </ul> AND <ul style="list-style-type: none"> <li>• Further discussion of items related to attention and impulse control confirms a concern in that area.</li> </ul>
Strengths and Difficulties Questionnaire (SDQ)	<ul style="list-style-type: none"> <li>• Total symptom score of <math>&gt;19</math>.</li> <li>• Hyperactivity scale score of 7–10 (see instructions at <a href="http://www.sdqinfo.com">www.sdqinfo.com</a>).</li> <li>• Impact scale (back of form) score of 1 (medium impairment) or <math>\geq 2</math> (high impairment).</li> </ul> AND <ul style="list-style-type: none"> <li>• Further discussion of items related to attention and impulse control confirms a concern in that area.</li> </ul>

setting from the time symptoms are recognized, even if the child's symptoms do not rise to the level of a disorder or referral to a mental health specialist is ultimately part of the care plan.

### Engage Child and Family in Care

Without engagement, most families will not seek or persist in care. The process may require multiple primary care visits.

Reinforce strengths of the child and family (eg, good relationships with at least 1 parent or important adult, prosocial peers, concerned or caring family, help-seeking, connection to positive organizations) as a method of engagement, and identify any barriers to addressing the problem (eg, stigma, family conflict, resistance to treatment). Use “common factors” techniques to build trust and optimism, reach agreement on incremental next steps, develop a plan of care, and collaboratively determine the role of the primary care physician. A key step is to reach agreement that there is a reason to consider intervention, and, ideally, that there are concrete problems that the family would like to see addressed. Regardless of other roles, the primary care physician can encourage a positive view of treatment on the part of the child and family.

### Offer Psychoeducation About ADHD, the Differential Diagnosis, and the Process of Arriving at a Diagnosis

Parents have likely heard about ADHD from other sources; their knowledge and concerns about the conditions may vary widely. They may have worries about being coerced into labeling their child with the condition by demands from the pediatrician or schools. The clinician can ask about what they know and what questions they may have. She can explain the process of making a provisional diagnosis and investigating alternatives, including language and learning problems, anxiety, and normal variation in development and temperament. Perhaps most importantly, the clinician can assure parents that she will not be jumping to a diagnosis, but rather will work with them to collect relevant information, make a plan of treatment,

and then reevaluate the situation as time goes on. At some point, parents will also want to know more about the natural history of the condition and the implications it may have for their child's future. It is reasonable to say that these sorts of problems are common and highly amenable to treatment of various kinds, and, while sometimes persistent, tend to be more easily managed as the child gets older.

### Encourage Healthy Habits

Regular exercise and outdoor play are beneficial to all children and may be particularly helpful to inattentive and impulsive children. These children may also benefit from participation in structured sports activities, which offer exercise as well as the opportunity to build social skills such as taking turns, following rules, and handling success and disappointment. Also important are regular sleep habits, special time with parents, praise for good behavior, and reinforcement of the child's strengths. Limiting media exposure may be particularly important for these children. Television programs, movies, and computer games can be overstimulating; long hours in these activities can produce irritability. Unrestricted access to a television or computer, especially in the child's bedroom, can contribute to loss of sleep, failure to do homework, and the risk of seeing programming that contributes to increased activity.

### Reduce Stress

Consider the child's social environment (eg, family social history, parental depression screening, results of any family assessment tools administered, reports from child care or school). Symptoms of inattention and hyperactivity will generally worsen in stressful settings. The physician can guide parents in providing a safe, structured environment and coach parents in working constructively with the child's school. The physician can also address stresses on family members—if they have problems with mood or irritability, they will have more difficulty adapting to and moderating the child's behavior.

### Offer Initial Intervention(s)

The strategies described in the following text are common elements of evidence-based and evidence-informed

**Table 168-2** Conditions That May Mimic or Co-occur With Inattention and Impulsivity

CONDITION	RATIONALE
Hearing or vision problems Sleep deprivation	All children who seem inattentive should be screened for sensory deficits.  Sleep problems can cause inattention and irritability. Attention-deficit/hyperactivity disorder (ADHD) may contribute to difficulty sleeping.
ADHD	Diagnosis requires that a child have a persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development. These patterns are characterized as 6 or more symptoms of inattention (eg, careless with detail; fails to sustain attention; seems not to listen; does not finish instructed tasks; poor self-organization; avoids tasks requiring sustained mental effort; loses things; easily distracted; and seems forgetful) or hyperactivity [eg, fidgets; leaves seat when should be seated; runs or climbs excessively and inappropriately; noisy in play; persistent motor activity unmodified by social context (but this is seen less in teens); talks excessively; blurts out answers before question completed; fails to wait turn; and interrupts others' conversation or games] for at least 6 months. Further features necessary to make this diagnosis include the following: <ul style="list-style-type: none"> <li>• These symptoms were present prior to age 12 years.</li> <li>• These symptoms are present in at least 2 types of settings (eg, home and school).</li> <li>• The symptoms cause significant distress or impaired functioning.</li> <li>• The symptoms are not better explained by another psychiatric disorder.</li> </ul>
Learning problems or disabilities	If symptoms of inattention and impulsivity are associated with problems of school performance, the child may be experiencing learning difficulties. See Chapter 172, Learning Difficulty, to explore this possibility.
Developmental problems	Children with overall intellectual or social limitations may seem less able to control their impulses and to focus and maintain their attention than their age-mates.
Language impairment or disorder	Children with receptive or expressive language impairment may be frustrated and inattentive at least in part because of difficulty understanding what others say or being able to express themselves. Similar problems can arise when children are learning a new language and cannot yet fully function at the level of their peers or teachers.
Depression	May co-occur with ADHD. Marked sleep disturbance, disturbed appetite, low mood, or tearfulness could indicate that a child is depressed as well as having attention difficulties. See Chapter 137, Depression.
Exposure to adverse childhood experiences (ACE)	Children who have experienced or witnessed trauma; violence; a natural disaster; separation from a parent; parental divorce or separation; parental substance use; neglect; or physical, emotional, or sexual abuse are at high risk of developing symptoms suggesting inattention and impulsivity. These symptoms may mask or be expressions of emotional difficulties such as adjustment disorder or posttraumatic stress disorder (PTSD). Some symptoms of PTSD may resemble symptoms of ADHD (eg, hypervigilance may mimic hyperactivity, or dissociation may mimic inattention). These children may also manifest other forms of anxiety. Inquiring about previous trauma in a confidential setting is important. See Chapter 129, Anxiety.
Anxiety	Anxious children may experience difficulty concentrating. See Chapter 129, Anxiety.
Bereavement	Most children will experience the death of a family member or friend sometime in their childhood. Other losses may also trigger grief responses—separation or divorce of parents, relocation, change of school, deployment of a parent in military service, breakup with a girlfriend or boyfriend, or remarriage of parent. Such losses are traumatic. They may result in such symptoms as sadness, anxiety, difficulty concentrating, poor impulse control, or academic decline immediately following the loss and, in some instances, more persistently. See also Chapter 137, Depression and the discussion of PTSD in Chapter 129, Anxiety.
Physical illness	Medical issues that can mimic or provoke symptoms of inattention and impulsivity include thyroid disease, hypoglycemia, hyperglycemia, side effects of medications (eg, bronchodilators), and endocrine tumors (eg, rarely pheochromocytoma).
Substance use	Children with symptoms of inattention and impulsivity may self-medicate with alcohol, nicotine, or other drugs. Conversely, children using substances may manifest inattention, impulsivity, and deteriorating school performance.
Conduct or oppositional disorders	See Chapter 139, Disruptive Behavior and Aggression, to differentiate these symptoms from problems of inattention and impulsivity and ADHD.
Tourette syndrome	Children with repetitive movements (tics) should be identified. In children with Tourette syndrome, ADHD symptoms may precede onset of tics. Stimulant medication may worsen tics. It is important to tailor treatment to the child's most pressing symptoms before deciding the risks and benefits of using stimulants in children with both problems.

Derived from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Arlington, VA: American Psychiatric Association; 2013

psychosocial interventions for management of children's behavior. They are applicable to the care of children with mild or emerging symptoms of inattention and impulsivity and to those with impairing symptoms that do not rise to the level of a disorder. They can also be used along with other specific interventions for ADHD.

*Guide parents in managing the child's behavior.* Good practices include the following:

- **Tangible rewards:** Rewards or privileges contingent on performance of routine tasks (eg, TV or computer time contingent on attaining a realistic goal). These rewards are most effective when coupled with a system for helping the child be aware of his or her own level of functioning, including charts that monitor events such as completion of homework without a reminder, staying "on-task" in school for a prearranged time before taking a break, carrying out chores at home before being asked.
- **Parent praise:** Conscious effort by parent to identify and comment on positive aspects of child's behavior (eg, compliment child, especially when desired action is spontaneous).
- **Parent monitoring:** Use of some systematic means to rate the child's burden of specific ADHD symptoms and overall social, emotional, and academic function (eg, weekly use of Vanderbilt scales or a customized checklist, often with simultaneous teacher ratings). Monitoring helps the parent advocate for the child and can help take pressure off the child by giving short-term, objective measures of progress.
- **Time-out:** Avoiding reinforcement of undesired behavior through arguing or allowing the behavior to continue (eg, child is required to sit without attention or activity for a brief period as a consequence for an undesired behavior).
- **Commands/limit setting:** Use of clear, simple commands that ideally give the child a warning of impending expected behavior, an opportunity to perform it, a warning of consequences for nonperformance, and a consistent consequence (eg, "You can do 1 more puzzle and then we have to go...now it's time to go...if you don't put the puzzle away now, you can't chose the music we listen to in the car.>").

*If there are battles over homework, offer guidelines.* Box 168-2 provides suggestions for parents to consider in addressing homework issues.

*If child meets diagnostic criteria for ADHD, consider specific therapy.* The course of treatment depends on the child's age and should be noted in the overall care plan.

For preschool-aged children (4–5 years of age), evidence-based, parent- or teacher-administered behavior therapy is considered the first line of treatment. Use of medications may be considered—ideally with specialist consultation—if behavioral treatment does not provide sufficient improvement or if evidence-based treatment is not available.

For elementary school-aged children (6–11 years of age), US Food and Drug Administration–approved medications for ADHD and/or evidence-based parent- and/or teacher-administered behavior therapy is considered first-line treatment for ADHD, preferably both. The evidence is particularly strong for stimulant medications and sufficient but less strong for atomoxetine, extended-release guanfacine, and extended-release clonidine (in that order).

### BOX 168-2 Strategies for Working Constructively With a Child's School

- Obtain consent for the clinician to exchange information with the child's teacher.
- Establish constructive 3-way (parent, teacher, pediatrician) communication with the school.
- Ask if testing has been requested and taken place to detect special educational needs.
- Monitor academic progress, helping to reinforce successes and identify particular subjects or educational settings where more support is needed.
- Advocate for appropriate classroom strategies.
  - Have the child sit at the front of the class.
  - If possible, engage the child in active learning, (eg, have the child go to the blackboard to write answers to questions).
  - Give extra time to stay organized (eg, write down assignments, make sure that all needed materials are taken home or gathered for a project, have the child repeat back what he or she is to do).
  - Break longer assignments into shorter pieces (also helpful for homework).
  - Coordinate reports of behavior with home—consider a daily report card of behavior and subsequent rewards or consequences.

For adolescents (12–18 years of age), Food and Drug Administration–approved medications for ADHD with the assent of the adolescent along with behavior therapy are considered treatment for ADHD.

### Provide Resources

Families may find support and resources from organizations such as Children and Adults With Attention-Deficit/Hyperactivity Disorder ([www.chadd.org](http://www.chadd.org)). Helpful publications are included in Tools for Practice: Engaging Patient and Family at the end of this chapter. Provide the family with contact numbers and resources in case of emergency.

### Monitor the Child's Progress Toward Therapeutic Goals

Child care, preschool, or school reports can be helpful in monitoring progress. The Vanderbilt scales (parent and teacher), SDQ (parent, teacher), and Pediatric Symptom Checklist (PSC) can be helpful in monitoring progress with symptoms and functioning. Both medications and behavioral treatments need careful titration to achieve their desired effects without the development of side effects. The need for higher-than-recommended doses of medication could be a sign of difficulties with adherence or a need to switch to a different medication. Behavioral treatments can be difficult to implement and maintain. Physicians can work with families to adapt behavioral suggestions to family circumstances and to explore barriers to other aspects of treatment, including effective engagement with schools.

It is important for the clinician to help the family understand that it is not uncommon for treatment to

### BOX 168-3 American Academy of Pediatrics Recommendations for Treatment of Attention-deficit/Hyperactivity Disorder

- Recommendations for treatment of children and youth with ADHD vary depending on the patient's age.
  - For *preschool-aged children (4–5 years of age)*, the primary care clinician should prescribe evidence-based parent- and/or teacher-administered behavior therapy as the first line of treatment (quality of evidence A/strong recommendation) and may prescribe methylphenidate if the behavior interventions do not provide significant improvement and there is moderate-to-severe continuing disturbance in the child's function. In areas in which evidence-based behavioral treatments are not available, the clinician needs to weigh the risks of starting medication at an early age against the harm of delaying diagnosis and treatment (quality of evidence B/recommendation).
  - For *elementary school-aged children (6–11 years of age)*, the primary care clinician should prescribe FDA-approved medications for ADHD (quality of evidence A/strong recommendation) and/or evidence-based parent- and/or teacher-administered behavior therapy as treatment for ADHD, preferably both (quality of evidence B/strong recommendation). The evidence is particularly strong for stimulant medications and sufficient but less strong for atomoxetine, extended-release guanfacine, and extended-release clonidine (in that order) (quality of evidence A/strong recommendation). The school environment, program, or placement is a part of any treatment plan.
  - For *adolescents (12–18 years of age)*, the primary care clinician should prescribe FDA-approved medications for ADHD with the assent of the adolescent (quality of evidence A/strong recommendation) and may prescribe behavior therapy as treatment for ADHD (quality of evidence C/recommendation), preferably both.
- Primary care clinicians should titrate doses of medication for ADHD to achieve maximum benefit with minimum adverse effects (quality of evidence B/strong recommendation).

For more information, see American Academy of Pediatrics Subcommittee on Attention-Deficit/Hyperactivity Disorder, Steering Committee on Quality Improvement. ADHD: clinical practice guideline for the diagnosis, evaluation, and treatment of attention-deficit/hyperactivity disorder in children and adolescents. *Pediatrics*. 2011;128(5):1007–1022 ([pediatrics.aappublications.org/content/128/5/1007](http://pediatrics.aappublications.org/content/128/5/1007)).

Adapted from *Caring for Children With ADHD: A Resource Toolkit for Clinicians*. Copyright 2011 American Academy of Pediatrics.

be successful for a period and then seem to lose effectiveness. This can happen when there are new stresses or demands, or when, after a period of success, there has been a letup on treatment. If modifying existing treatment and exploring ways of dealing with new stresses do not help get function back to baseline, then new treatments, or new diagnoses, need to be considered. In particular, as school demands increase, learning issues may need to be considered even if they were not seen as contributing problems in the past.

#### Involve Specialist(s)

*Involve specialist(s) if the child does not respond to initial interventions or if the following clinical circumstances exist:*

- Child has severe functional impairment.
- Child has severely disruptive behavior or aggression.
- Child has comorbid depression or posttraumatic stress disorder, or if problems with mood, behavior, and development seem more prominent than difficulties with attention or impulsivity.
- Symptoms are threatening school performance or the achievement of other developmentally important goals (eg, developing and sustaining friendships).
- The child or parent is very distressed by the symptom(s).
- There are co-occurring behavior problems. (The combination of shyness, anxiety, and behavior problems is thought to be particularly risky for future behavior problems of a more serious nature.)
- The child's symptoms were preceded by serious trauma.
- The child has ADHD and contraindications to stimulants or marked side effects with stimulants.
- The child's problems are occurring in the context of other family emotional or behavioral problems that

have not been alleviated with primary care interventions.

*When specialty care is needed, ensure that it is evidence-informed and assist the family in accessing it.* Pharmacologic interventions and a number of evidence-based and evidence-informed psychosocial interventions are available for the treatment of ADHD in children and adolescents. Ideally, those referred for care in the mental health specialty system would have access to the safest and most effective treatments. Box 168-3 provides a summary of these interventions. Youth referred for mental health specialty care complete the referral process only 61% of the time, and a significantly smaller number persist in care.

Note that not all evidence-based interventions may be available in every community. If a particular intervention is not available, this becomes an opportunity to collaborate with others in the community to advocate on behalf of children. Increasingly, states offer both telepsychiatry services and consultation/referral support “warmlines” that help physicians provide initial treatment and locate resources. The availability of the latter form of help is tracked at the National Network of Child Psychiatry Access Programs ([www.nncpap.org](http://www.nncpap.org)).

*Reach agreement on respective roles in the child's care.* If the child is referred to mental health specialty care, the physician may be responsible for initiating medication or adjusting doses; monitoring response to treatment; monitoring adverse effects; engaging and encouraging the child's and family's positive view of treatment; and coordinating care provided by parents, school, medical home, and specialists. In fact, the child may improve just knowing that the clinician is involved and interested. Resources available to help clinicians in these roles are provided in Tools for Practice: Medical Decision Support.

## Chapter 169

# IRRITABILITY AND FUSSINESS

Diana King, MD; Waseem Hafeez, MBBS

Irritability, “a condition in which a person, organ, or a part responds excessively to a stimulus,” is a common complaint in children, especially in neonates and infants. Although experienced physicians can recognize irritability in a child, a concise definition is difficult because some subjectivity exists in the use of the term. Although it is not a quantifiable symptom, irritability includes episodes of crying or fussiness despite attempts at comforting the infant. While it is not a

symptom of any specific illness, most parents recognize that something might be wrong with the child even though other symptoms may not yet exist.

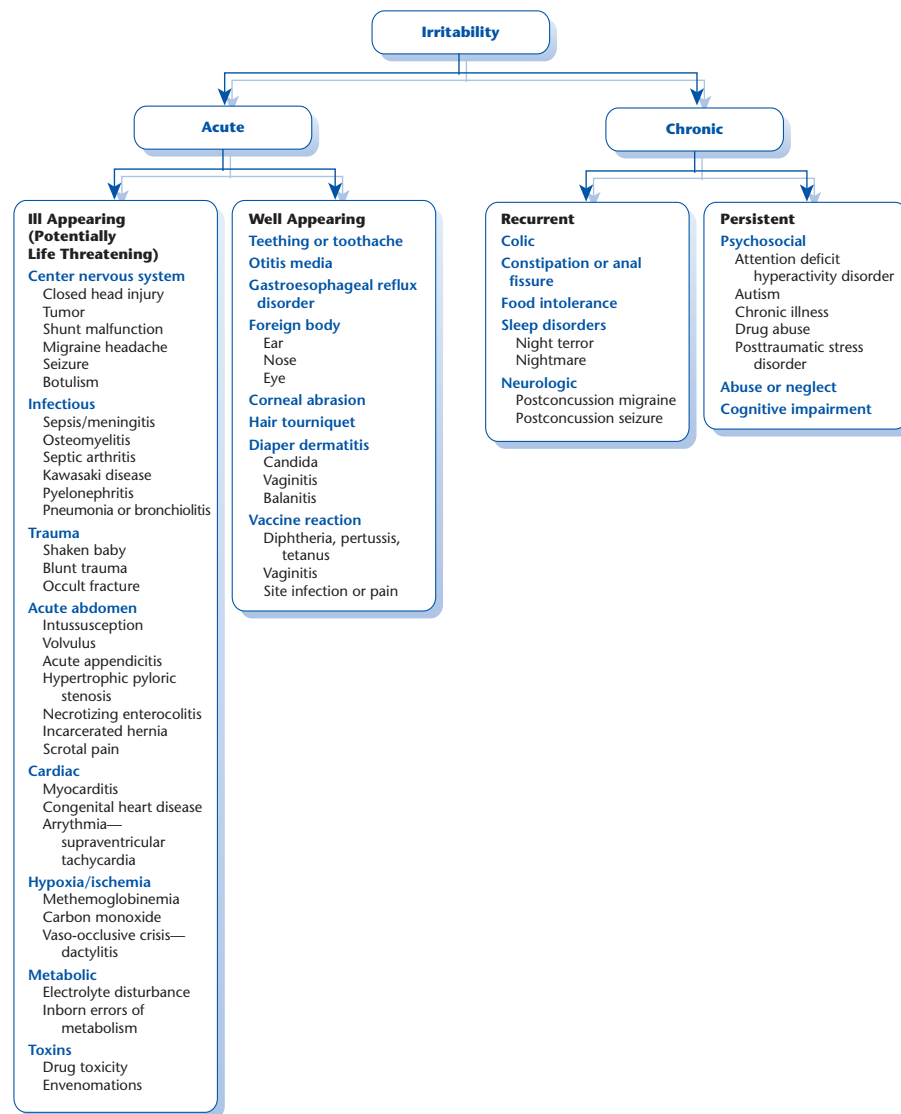

Irritability results from lack of vital nutrients (eg, oxygen, glucose), the presence of noxious stimuli (eg, pain, toxins), or an emotional state (eg, anger, frustration). It may have different causes and manifestations in infants, children, and adolescents. Whereas older children and adolescents may offer explanations that help clarify their complaint, an infant or preverbal child is unable to provide such information. Acute irritability may be associated with life-threatening illnesses requiring urgent intervention and stabilization before a search for the cause begins. A parent who seeks care for an infant who is fussier than usual may arrive with the child in shock, in respiratory distress, or having a seizure. An organized approach to the differential diagnosis minimizes unnecessary testing. If the child does not have an immediately life-threatening condition, then a complete history and thorough physical examination are the first steps in the evaluation of irritability and, in many cases, will reveal the cause of the symptom. Many common infectious, traumatic, toxic, allergic, and inflammatory conditions can be diagnosed by history and physical examination alone. Laboratory or radiologic procedures may confirm a clinical suspicion. An algorithm to differentiate some life-threatening conditions from less serious causes of irritability is presented in Figure 169-1.

## ACUTE IRRITABILITY IN THE ILL-APPEARING CHILD

### Central Nervous System

Children younger than 2 years have a high risk for significant brain injury after both accidental and non-accidental traumatic brain injury (TBI). In data collected between 2002 and 2006, the National Center for Injury Prevention and Control found that children aged 0 to 4 years had the highest rate of TBI-related emergency department visits (1,256 per 100,000 population), with falls, motor vehicle crash, and inflicted trauma as the leading causes. The incidence of intracranial injury was 13% in infants 0 to 2 months of age, 6% in infants 3 to 11 months of age, and 2% in infants 12 months or older. The American Academy of Pediatrics has recommended guidelines for evaluation and management of head injury in this age group. A history of a fall from the bed, infant-walker, stairs, or bicycle can often be obtained. To determine the need for computed tomography scan in clinically important TBI, prediction rules have been identified which include in children younger than 2 years abnormal mental status, loss of consciousness, scalp hematoma except frontal, palpable skull fracture, severe mechanism of injury, and not acting normally according to the parents. In addition to these findings, the prediction rule for children aged 2 years and older also includes vomiting, severe headache, and signs of basilar skull fracture.

A special concern is for children who sustain concussions from sports-related injuries. The American Academy of Neurology defines concussion as “a

**Figure 169-1** Algorithm for evaluation of the irritable infant.

trauma-induced alteration in mental status that may or may not involve loss of consciousness.” The term *post-concussive syndrome* refers to the constellation of acute symptoms, which can be somatic (headache, dizziness, blurriness), emotional (irritability, anxiety), and cognitive (concentration and memory difficulties). The term *second impact syndrome* has been proposed for an athlete who has sustained a concussion, sustains a second head injury before symptoms associated with the first have fully cleared, and is at risk for a catastrophic outcome such as permanent disability or death. To manage these injuries, a concussion grading scale has been developed with return-to-play guidelines that include physical and cognitive rest and rehabilitation.

Increased intracranial pressure (ICP) from a brain tumor may produce acute irritability and altered behavior without the usual preceding symptoms such as headache or loss of coordination and ataxia. Primary

brain tumors in the posterior fossa are the most common solid malignancies in infants and children younger than 7 years. In young children, the diagnosis of a brain tumor may be delayed because their symptoms are subtle (headache, irritability, or drowsiness) or similar to those of more common illnesses, such as gastrointestinal disorders (vomiting). Hydrocephalus, another cause of raised ICP, often occurs in infancy with irritability, vomiting, a tense or bulging fontanel, and an increasing head circumference that crosses percentile lines. Older children usually complain of headaches. Neuroimaging shows congenital malformation (myelomeningocele, Chiari syndrome, Dandy Walker malformation, aqueductal stenosis, arteriovenous malformation) or germinal matrix intraventricular hemorrhage of prematurity. Hydrocephalus is treated by the introduction of ventriculoperitoneal shunts to reduce the ICP. The ventriculoperitoneal shunt may become obstructed or infected, or it may malfunction,

causing overdrainage or underdrainage, initially causing irritability, headache, vomiting, or lethargy.

Undiagnosed migraine headache may manifest itself in the preverbal child with irritability. Headaches attributable to migraine occur in 8% to 12% of children younger than 3 years. There seems to be an association of infantile colic with excessive crying and irritability with later diagnosis of migraine. Children with seizures, especially unwitnessed, may seem irritable during an aura or the postictal phase. Neonatal seizures, more commonly seen in preterm infants than term infants, may have only subtle symptoms such as ocular or pedaling movements, lip smacking, or apnea. Nonconvulsive status epilepticus, which includes absence and partial complex seizures, is a relatively rare cause of abnormal behavior resulting from continuous or intermittent seizure activity in the absence of any motor component. The hallmark of nonconvulsive status epilepticus is a diagnostic electroencephalogram associated with irritability and a change in behavior or mental status.

Infant botulism, most commonly foodborne, may initially cause difficulty in feeding, irritability, lethargy, weak cry, and constipation. As the disease progresses, drooling, dysphagia, loss of head control, respiratory distress, and flaccid paralysis may occur from progressive bulbar involvement.

### Infections

The primary care physician should suspect a bacterial infection in a child with fever and irritability. Infants with meningitis may have irritability, lethargy, and poor feeding. If the fontanel is still open, then it may be bulging. Lumbar puncture is diagnostic, and treatment with intravenous antibiotics should not be delayed. The introduction of vaccines against *Haemophilus influenzae* type B and *Streptococcus pneumoniae* has changed the epidemiology of bacterial meningitis in children. Infants younger than 3 months of age are most commonly infected with Group B streptococci and gram-negative bacilli. Encephalitis from herpes simplex virus should also be considered. In children older than 3 months, the most common pathogens are *Streptococcus pneumoniae* and *Neisseria meningitidis*.

Irritability and decreased movement of a limb should raise concern for osteomyelitis. Swelling and erythema of the soft tissue overlying the bone may exist, often with a history of preceding trauma. Joint pain, fever, irritability, and a limp should raise concern for septic arthritis. Examination will reveal erythema, swelling, or warmth over the affected joint, with restricted movement. With septic arthritis of the hip, swelling and redness may not be visible, and the pain may be referred to the knee. Blood should be analyzed for culture, complete blood count, and C-reactive protein to help establish a diagnosis. An orthopedist should be consulted for possible surgical drainage.

Irritability is one of the most common associated symptoms in children with Kawasaki disease. The principal clinical manifestations of this systemic vasculitis are fever, rash, conjunctival injection, erythema of lips and mouth, cervical adenopathy, and changes in the extremities. Bacteremia and urinary tract

infections can also produce irritability, along with fever in an ill-appearing infant.

### Trauma

A systematic search for injuries should be performed on any child with a history of trauma. Inflicted injuries are more difficult to diagnose because the signs may be subtle and the history is often misleading. Abusive head trauma is the leading cause of traumatic death in children younger than 2 years. The rotational forces sustained during shaking cause movement of the brain within the subdural space and tearing of the bridging veins, resulting in subdural hematoma. The shearing forces can also cause diffuse axonal injury. Clinical signs of abusive head trauma may be poor feeding, vomiting, lethargy, or irritability. More severe central nervous system dysfunction can result in death.

In infants and young children, the pressure of the lap belt of a restraint system in a motor vehicle crash or other blunt abdominal trauma can lead to intra-abdominal bleeding, initially displayed as irritability from tissue hypoperfusion and pain. Many traumatic causes of irritability that are not life threatening may be apparent on initial physical examination and include fractures and dislocations.

### Acute Abdomen

Intussusception is seen most often between the ages of 3 months and 5 years, with a peak incidence at 6 to 11 months. The child seems colicky, cries, and may draw the knees toward the chest; this episode may last a few minutes and then subside. The child often looks better between episodes, but the irritability gradually increases and vomiting becomes more frequent and sometimes bilious. Mandeville et al found the classic triad of intermittent colicky abdominal pain, vomiting, and bloody stools was present in more than 65% of patients; and in patients younger than 12 months, irritability was an important clinical predictor.

Appendicitis is the most common condition requiring emergency surgery in children. Abdominal pain in a young child may first manifest as irritability, before the appearance of nausea, vomiting, fever, and right lower quadrant tenderness. Perforation rates for appendicitis are higher in children than in adults (30%–65%), and, given that the omentum is less developed in children, perforations are less likely to be walled off or localized.

Hypertrophic pyloric stenosis may become symptomatic as early as the first week of life and as late as the fifth month. Symptoms begin with nonbilious vomiting after feeding, and as the disease progresses the vomiting becomes projectile. The baby may initially seem normal, but hunger makes the infant irritable, and signs of dehydration eventually become apparent. The finding of an olive shaped mass in the right upper quadrant of the abdomen is diagnostic, and confirmed by ultrasound.

Malrotation with midgut volvulus peaks during the first month of life but can occur any time in childhood. The neonate will be irritable initially; as the bowel becomes obstructed and necrotic, bilious vomiting and shock may result from perforation.

Necrotizing enterocolitis is typically seen in premature infants in their first few weeks of life. It may rarely be seen in full term infants, within the first 2 weeks after birth, particularly with a stressor such as infection or anoxic event. Infants are ill appearing, irritable, and lethargic, with distended abdomen and bloody stools. Abdominal plain-film finding of pneumatosis intestinalis, caused by gas in the submucosal intestinal wall, is diagnostic of necrotizing enterocolitis with ultrasound becoming increasingly used to make the diagnosis while avoiding radiation. Because of a high mortality rate, management includes early surgical consultation and aggressive fluid resuscitation, bowel rest, and broad-spectrum antibiotic coverage.

Sixty percent of incarcerated inguinal hernias occur during the first year of life, especially in infants born preterm, with symptoms of irritability, vomiting, and pain in the groin and abdomen. A testicular examination is imperative in all male patients with irritability or abdominal pain. On examination a nonfluctuant tender mass is present in the inguinal region and may extend down into the scrotum. With the onset of ischemia of the involved bowel the pain becomes more intense and localized to the scrotum, and the infant may have bilious vomiting with the presence of bloody stools. An attempt should be made to reduce the incarcerated hernia manually by gentle compression. Sedation or analgesia, elevation of the lower torso, and an ice pack may be helpful. If reduction is unsuccessful or the child shows signs of small bowel obstruction, then operative reduction of the incarcerated hernia should be performed. Irritability with scrotal pain may also result from epididymitis, torsion of the testis, or torsion of the appendix testis.

### Cardiac System

Acute myocarditis can be a challenging diagnosis to make because the clinical presentation can vary. The diagnosis should be considered in an irritable child with resting tachycardia and respiratory symptoms. An electrocardiogram may reveal sinus tachycardia, ventricular hypertrophy, and ST and T wave changes. Low voltage QRS complexes, or an abnormal QRS axis, may be present. Chest radiograph may reveal cardiomegaly, pulmonary edema, or pleural effusion. Elevated C-reactive protein, serum troponin, and aspartate aminotransferase levels will support the diagnosis, and an echocardiogram will show reduced ventricular function. Cardiac magnetic resonance is a noninvasive method to confirm the diagnosis, but the gold standard is an endomyocardial biopsy. The presence of immune complexes indicates an immune-mediated process, and immunosuppressive therapy may be indicated. Treatment includes inotropic support, diuretics, and afterload reducers in a critical care setting.

Anomalous left coronary artery originating from the pulmonary artery (ALCAPA) is a congenital abnormality that can present in early infancy with irritability, poor feeding, and difficulty breathing. The electrocardiogram may reveal abnormal Q waves in leads  $V_4$ - $V_6$ , I and aVL, or an abnormal R wave progression.

An infant with supraventricular tachycardia may present with irritability, poor feeding, vomiting, cyanosis,

or pallor. Physical examination will reveal a rapid, regular rhythm; electrocardiogram is diagnostic.

### Hypoxic or Ischemic Events

Carbon monoxide (CO) poisoning and methemoglobinemia cause irritability by producing hypoxia. CO binds to hemoglobin with an affinity more than 200 times that of oxygen, whereas methemoglobin is unable to bind to oxygen. Both actions result in a leftward shift of the oxygen-hemoglobin dissociation curve and decreased oxygen delivery to the tissues. A history of smoke inhalation and exposure to an indoor gas stove or to automobile exhaust fumes may not be forthcoming without prompting. Early findings with CO poisoning are similar to influenza-like symptoms of headache, irritability, and dizziness, whereas prolonged exposure may result in altered mental status. Arterial measurement of carboxyhemoglobin is diagnostic.

Methemoglobinemia in infancy may be either hereditary or related to hypoxic events, medication use (sulfonamides, topical anesthetics, metoclopramide), products containing nitrites and nitrates (contaminated well water or foods with naturally occurring nitrates such as spinach, green beans, carrots, and squash), or to diarrhea, probably from the nitrite-forming bacteria in the gut. Hereditary methemoglobinemia is usually mild, whereas the acquired disease can be life threatening. The hallmarks of methemoglobinemia are characteristic blue-gray cyanosis that is not improved with oxygen despite normal arterial oxygen tension and chocolate brown appearance of arterial blood. Pulse oximetry will not be reliable as high levels of methemoglobin will tend to cause a pulse oximeter reading of about 85% regardless of the true level of oxygen saturation. Treatment of the patient begins with 100% supplemental oxygen by non-rebreather mask and aggressive supportive care. In CO poisoning, hyperbaric oxygen therapy may be indicated in certain clinical conditions; methylene blue is an effective treatment for methemoglobinemia.

In children with sickle cell anemia, ischemia may cause painful vaso-occlusive crisis. The first presentation in infants and younger children is usually irritability and dactylitis (painful swelling of the hands and feet) as a result of vascular stasis and ischemia. Treatment includes analgesia, hydration, and rest.

### Metabolic System

Hypoglycemia, hypo- or hyponatremia, hypo- or hypercalcemia, hypomagnesemia, and inborn errors of metabolism can all cause irritability. Hypoglycemia is defined as a glucose level of 40 mg/dL or less and can be a primary process or caused by sepsis, ingestion, or cardiac or respiratory failure. Rapid detection and treatment of hypoglycemia can prevent irreversible neurologic damage. Hyponatremia can result from gastrointestinal losses or water intoxication, whereas hyponatremia is seen with diarrhea in which the water losses exceed salt loss, when replacement fluid has too high a sodium content, or with improper preparation of infant formula. Hypocalcemia in the newborn period may cause irritability, poor feeding, and lethargy; later in infancy and during childhood, hypocalcemia is seen with rickets. Hypercalcemia is a rare

electrolyte disturbance resulting from hyperparathyroidism, vitamin D intoxication, or idiopathic causes. Hypomagnesemia is found with hypocalcemia.

The inborn errors of metabolism that cause irritability are those in which a toxic intermediate accumulates. Organic and aminoacidemias and urea cycle disorders result in metabolic acidosis or hyperammonemia. They are symptomatic in the first few weeks of life, with vomiting, poor feeding, irritability, and lethargy. When a milder degree of enzyme dysfunction is present, clinical disease may be triggered by a bacterial or viral illness.

### Toxins and Drugs

Life-threatening intoxication may result from heavy metals such as lead and mercury, drugs of abuse such as cocaine and alcohol, envenomation by scorpions and snakes, overdoses of or idiosyncratic reactions to medications, and contact with agricultural, industrial, or household chemicals. Thorough questioning about recent use of lawn chemicals, pesticides, and cleaning products may be the only clues to these factors as a cause of irritability because many of these chemicals will not be detected by standard toxicologic screenings of blood and urine. Prescribed or over-the-counter medications such as beta-agonists, antiepileptics, decongestants, antihistamines, antitussives, and various cold preparations may cause irritability even when used as directed and certainly when overused. Cocaine, alcohol, phencyclidine hydrochloride, inhalants, and other drugs of abuse are known to cause irritability. Infants and children may be exposed to these substances by passive means transplacentally, by ingestion of breast milk, or by inhalation. They may accidentally ingest alcohol, cigarettes, or other substances left within reach. A positive history may be difficult to elicit, and a toxicologic screen may not always be helpful; thus a strong index of suspicion is needed. Substance use or withdrawal should be considered in the differential diagnosis of any adolescent with chronic persistent irritability. In rare instances, intentional poisoning may be the cause of a child's distress.

### Malignancy

Many physicians remember at least 1 child who has had complaints of irritability and intermittent fever in whom leukemia with bone pain was diagnosed. Malignancies of all sorts may have a component of irritability among their symptoms and must be considered carefully when no other diagnosis is forthcoming.

## ACUTE IRRITABILITY IN THE WELL-APPEARING CHILD

Irritability in infants has been attributed to a variety of causes of pain or discomfort that may become obvious during the evaluation. Dental caries and teething may cause an infant to be fussy or irritable. In addition to irritability, teething may be accompanied by loose stools but not fever. Cold teething rings may provide some relief, but numbing gels with benzocaine are less helpful and may be harmful as they have been associated with methemoglobinemia.

Acute otitis media is a common cause of irritability, with or without fever, in children younger than 2 years and in those attending child care. Also common, particularly in the first year of life, is gastroesophageal reflux, which may be asymptomatic or reveal itself with postprandial irritability, recurrent vomiting, and inadequate weight gain.

Other sources of irritability and nonspecific crying episodes may be related to a foreign body in the ear or nose, a corneal abrasion, hair wrapped around a digit or penis, diaper rash, nonspecific vaginitis, balanitis, insect and spider bites or stings, and pain from the site of a vaccination. A thorough head-to-toe examination, including special attention to the eyes, ears, digits, and genitalia, is essential to establish a diagnosis.

A foreign body in the ear or nose, if present for a prolonged period, results in foul-smelling discharge. If visible, the object may be removed with forceps, by gentle irrigation, or by suction; otherwise removal should be done under sedation or general anesthesia. Disk batteries need to be removed emergently because they may leak and can cause tissue destruction. An insect in the ear canal can make a child very irritable and may be removed after first killing the insect with mineral oil or lidocaine.

Foreign bodies under the eyelid, inward turned eyelashes, or a baby scratching the eyes may cause corneal abrasion. The child may be irritable, with increased tearing, conjunctival injection, and photophobia. Diagnosis is made by Wood lamp examination after instillation of fluorescein into the eye. A foreign body may be removed by a moistened cotton-tipped applicator or by irrigation.

A hair tourniquet around a child's digit or genitals can cause irritability and pain. A thorough examination in the creases of the digits is essential because prolonged constricting bands may compromise distal circulation.

In some instances the source of a child's irritability will be found only on thorough examination of the genitalia, which may reveal evidence of vaginitis, balanitis, or an anal fissure. Diaper dermatitis, common after a diarrheal illness, with *Candida* infection or as an allergic reaction to the diaper material, is another potential cause of irritability in infants.

Infants can certainly be irritable after the administration of a vaccine, with local erythema, swelling, and tenderness at the injection site. Persistent, inconsolable crying lasting 3 hours or more within 48 hours of receiving whole-cell pertussis DTP vaccine have been reported but is significantly lower with the newer acellular-pertussis DTaP vaccine.

## CHRONIC IRRITABILITY

Chronic irritability may be recurrent or persistent in a child and challenges both the parents' and the physician's skills. Psychosocial causes may top the list, but toxic, neurologic, metabolic, and miscellaneous causes must be considered and are shown in Figure 169-1. Irritability as a chronic feature of a child's behavior may indicate significant problems with familial relationships and the ability to master the environment. Infants may be irritable because of parental-infant temperament mismatches, maternal depression, or

stress within the family from, for example, the birth of a new child. Abuse and neglect of a child may provoke irritable behavior or outbursts. An older child or adolescent who has a psychiatric condition such as depression, psychosis, autism, posttraumatic stress disorder, or substance abuse may be described as irritable by parents and others. The investigation and treatment of irritability in these situations may require a multidisciplinary and long-term approach.

### Chronic Recurrent Irritability

Colic is characterized by paroxysms of irritability or crying that begin and resolve without apparent cause in infants younger than 5 months of age. Criteria for the diagnosis are episodes of crying lasting 3 or more hours per day, occurring 3 or more days per week for at least 1 week. Colic typically peaks at 6 weeks and abates by 3 to 4 months. The physical examination is normal, and growth and development are not affected.

Constipation in the older infant or child, another common cause of recurrent irritability, is associated with inadequate fluid intake, low-fiber diet, dietary changes, and toilet training. The passage of large, hard stools can result in anal fissures, which make the situation worse as the child becomes even more reluctant to defecate because of the pain.

Food allergy affects approximately 6% to 8% of infants and young children and approximately 3.5% to 4% of adults. The most common food allergens include cow's milk, eggs, peanuts, wheat, and shellfish. Milk protein allergy is usually seen in the first few months of life: children are irritable and have blood-streaked stools, although they are otherwise healthy. Treatment involves switching to hypoallergenic formulas derived from cow's milk then gradually advancing to an unrestricted diet by 9 to 12 months of age.

Night terrors, typically occurring between 2 and 4 years of age during nonrapid eye movement sleep, usually begin with sudden and prolonged periods of inconsolable crying and end spontaneously, with the child rapidly returning to sleep. A nightmare occurs during rapid eye movement sleep, characterized by a frightening dream, which fully awakens the child, and return to sleep is delayed. Vivid recollection of the dream occurs, appropriate to the child's developmental and maturational stage. (See Chapter 194, Sleep Disturbances, Nonspecific.)

Neurologic disorders, such as brain tumors, migraine headaches, seizures, and postconcussion syndrome, are causes of chronic or recurrent irritability among older children and adolescents. Postconcussion syndrome is particularly distressing to families because the head injury may have occurred months or years before and may even have seemed minor, yet the irritability and behavior changes may be a persistent and major complaint.

### Chronic Persistent Irritability

#### Psychosocial Disorders

Attention-deficit/hyperactivity disorder is the most commonly diagnosed biological-behavioral disorder of childhood, occurring in approximately 8% to 10% of school-aged children. The children may have coexisting

externalizing disorders (conduct disorder and oppositional defiant disorder) and internalizing disorders (depression and anxiety disorders). A common presentation in infants and young children may be irritability from frustration as a result of family and peer relationships, propensity to accidental injury, and difficulty with academic work.

Autism spectrum disorder usually first manifests itself in children younger than 3 years. Early symptoms include irritability, deficits in verbal and social interaction, repetitive behaviors, failure to participate within groups, and hours spent in solitary play.

Children with a chronic condition face stressors beyond their illness itself, such as altered physical development and appearance, high absenteeism, and inability of their peer groups to accept their disease. The investigation and treatment of irritability in this context may require a multidisciplinary and long-term approach.

### Children With Cognitive Impairments

Children with severe intellectual disabilities are unable to verbalize what they are experiencing and are left to endure pain more often than healthy children. Although their caregivers are usually adept at reading their child's body language and behaviors to know when the child is in pain, the parent is not always able to identify the specific cause. These children are likely to experience pain from the same sources as unimpaired children (teething, sore throat, headache, minor trauma) but are also at risk for additional sources of pain and discomfort. Muscle spasms, gastroesophageal reflux, constipation, and urinary tract infections are frequent causes of irritability. In children with spastic quadriplegia, pathologic fractures often occur as a result of decreased bone density, limb rigidity, and joint contractures. Children with intellectual disabilities often require treatment for seizures, respiratory conditions, and constipation with drugs that have a high incidence of behavioral side effects (irritability, aggression, and hyperactivity).

A wide variety of chronic disorders have irritability as a prominent or sole component. Hormonal effects associated with adolescence in both boys and girls can cause moodiness and irritability.

## SUMMARY

Irritability has a variety of causes and can be indicative of life-threatening or relatively trivial or transient disorders, which is why it elicits a high degree of concern. In an ill-appearing infant or child the initial task is stabilization followed by a thorough search for a cause. In a well-appearing infant or child an organized approach is needed to determine the source of the irritability. A complete history and thorough physical examination can most often determine the cause. In puzzling cases, serial examinations and staged laboratory investigations may be necessary.

## TOOLS FOR PRACTICE

### Engaging Patient and Family

- *Prevent Shaken Baby Syndrome* (handout), American Academy of Pediatrics (patiented. solutions.aap.org)

## Chapter 170 JAUNDICE

Debra H. Pan, MD; Yolanda Rivas, MD

*Jaundice* is a yellowish discoloration of the skin, sclerae, and mucous membranes resulting from deposition of the bile pigment bilirubin. The presence of jaundice on clinical examination indicates *hyperbilirubinemia*, which is defined as a total serum bilirubin greater than 1.5 mg/dL. In general, jaundice becomes evident at serum bilirubin concentrations greater than 3 mg/dL in older children and greater than 5 mg/dL in newborns.

Hyperbilirubinemia is typically characterized by the fraction of bilirubin that is increased, unconjugated (indirect), or conjugated (direct). Elevation of either of these fractions results in jaundice. Conjugated hyperbilirubinemia refers to a direct bilirubin greater than 2 mg/dL or greater than 20% of the total bilirubin

concentration. The presence of conjugated hyperbilirubinemia suggests hepatobiliary tract conditions.

### BILIRUBIN METABOLISM

To identify the cause of jaundice, the pediatrician or other physician must be familiar with the normal metabolism of bilirubin, which is the end product of heme degradation. Heme is produced from the breakdown of hemoglobin (70%–80%) and other hemoproteins (20%–30%). The conversion from heme to bilirubin follows a 2-step process that occurs mainly in the reticuloendothelial cells of the spleen, liver, and bone marrow. Heme is converted to biliverdin by the microsomal enzyme heme oxygenase and then to bilirubin by the cytosolic enzyme biliverdin reductase. This unconjugated bilirubin is a hydrophobic compound that is tightly bound to serum albumin and is transported to the liver for conjugation and clearance.

The metabolism of bilirubin follows 4 distinct steps: (1) The bilirubin is taken up across the sinusoidal (basolateral) membrane of the hepatocyte by a membrane receptor carrier. (2) Once inside the hepatocyte, the bilirubin binds to cytosolic glutathione S-transferase, historically known as ligandin. It is then conjugated with glucuronic acid by the enzyme bilirubin UDP-glucuronosyl transferase (BUGT) in the endoplasmic reticulum to form bilirubin monoglucuronides and diglucuronides. (3) Water-soluble bilirubin glucuronides are excreted into the bile through the apical canalicular membrane. This process is mediated by adenosine triphosphate-dependent transporters. Almost all the bilirubin in adult human bile is of the conjugated form, with bilirubin monoglucuronides accounting for 15% and diglucuronides accounting for 85%. In contrast, neonates have a higher concentration of bilirubin monoglucuronides in their bile because of a lower BUGT activity. The monoglucuronides are easily deconjugated and reabsorbed in the intestine. (4) The excreted bilirubin is further metabolized by bacterial flora to form urobilinoids, which are then eliminated in the feces, thus preventing the intestinal absorption of bilirubin.

Bilirubin glucuronides can also be deconjugated by bacteria or tissue  $\beta$ -glucuronidase in the intestine and then reabsorbed in the terminal ileum, a process known as *enterohepatic circulation*. Newborns are at high risk for bilirubin absorption from the intestine because of the high concentration of bilirubin monoglucuronides in their bile, the lack of intestinal bacterial flora to efficiently produce urobilinoids, and the high content of bilirubin and  $\beta$ -glucuronidase in meconium. Conditions that delay the passage of meconium can result in neonatal hyperbilirubinemia.

### SERUM BILIRUBIN

Serum bilirubin is conventionally measured by spectrophotometry based on the Van den Bergh (diazotization) reaction. Conjugated (direct) bilirubin reacts rapidly and unconjugated (indirect) bilirubin reacts slowly with diazo reagents. Indirect bilirubin is calculated as the difference between the total bilirubin and the direct bilirubin fraction. Although the terms *direct* and *conjugated* bilirubin are used interchangeably, direct

bilirubin actually consists of 2 components: conjugated bilirubin and  $\delta$ -bilirubin. In hepatobiliary obstruction, bilirubin glucuronides are not excreted properly from the hepatocyte into the bile. Under these circumstances, bilirubin glucuronides can reflux back into the systemic circulation and covalently bind to albumin. This conjugated bilirubin-albumin compound is known as  $\delta$ -bilirubin. Methods such as high-performance liquid chromatography can measure  $\delta$ -bilirubin as well as  $\alpha$ -,  $\beta$ -, and  $\gamma$ -bilirubin that corresponds to the unconjugated, monoconjugated, and diconjugated forms, respectively. Because of the long half-life of albumin,  $\delta$ -bilirubin accounts for the prolonged direct hyperbilirubinemia occasionally observed after restoration of normal bile flow.

## DIFFERENTIAL DIAGNOSIS

When discussing the differential diagnosis in a patient with jaundice, one should first categorize hyperbilirubinemia as either unconjugated or conjugated. It is helpful then to discuss each category separately in 2 different age groups: (1) newborns and young infants (infants <6 months), and (2) older infants (infants >6 months) and children. In general, unconjugated hyperbilirubinemia is common in neonates but relatively rare thereafter. Neonatal unconjugated hyperbilirubinemia is usually transient and benign, but marked increases of bilirubin can be toxic to the central nervous system. On the other hand, conjugated hyperbilirubinemia is always pathologic. When present in young infants, it is often related to primary hepatobiliary disorders, systemic or metabolic diseases, or genetic defects in bilirubin and bile acid metabolism or transport. In older children, viral hepatitis and drug- or toxin-induced liver damage are more prevalent.

## JAUNDICE IN NEWBORNS AND YOUNG INFANTS

A brief list of the causes of jaundice in newborns and young infants is presented in Box 170-1.

### Unconjugated Hyperbilirubinemia

The transition from intrauterine to extrauterine life is commonly associated with hyperbilirubinemia. Newborns have a total bilirubin level greater than the adults' normal limit of 1.5 mg/dL. More than half of newborns develop clinical jaundice in the first week of life, with most of them having unconjugated hyperbilirubinemia.

#### Increased Production of Bilirubin

Nonphysiologic jaundice should always be considered part of the differential diagnosis in neonatal jaundice. When evaluating patients with jaundice, factors such as early onset, rapid progression, and persistence of jaundice beyond 2 weeks of life always suggest a pathologic cause. In most instances, pathologic unconjugated hyperbilirubinemia results from either excessive production or abnormal hepatic clearance of bilirubin.

Hemolysis is the most common cause of excessive bilirubin production in neonates and is usually

### BOX 170-1 Differential Diagnosis of Jaundice in Newborns and Young Infants<sup>a</sup>

#### UNCONJUGATED HYPERBILIRUBINEMIA

##### Increased production of bilirubin

- Hemolysis (ABO-Rh incompatibility, erythrocyte defects, erythrocyte enzyme defects, disseminated intravascular coagulopathy)
- Polycythemia
- Cephalohematoma resorption

##### Decreased hepatocellular uptake or conjugation

- Prematurity
- Congenital hypothyroidism
- Physiologic jaundice of the newborn
- Breast milk jaundice
- Drug toxicity
- Gilbert syndrome, Crigler-Najjar syndrome

#### CONJUGATED HYPERBILIRUBINEMIA

##### Liver diseases

- Acute liver damage (ischemia, hypoxia, acidosis)
- Infection (sepsis, TORCH [toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex])
- Viral or other hepatitis
- Parenteral nutrition associated liver disease
- Metabolic liver disease (galactosemia, neonatal hemochromatosis,  $\alpha_1$ -antitrypsin deficiency, tyrosinemia, mitochondrial defects)
- Hormones and drugs

##### Obstruction of biliary system

- Congenital anomalies (biliary atresia, choledochal cyst)

##### Defects of bilirubin metabolism or transport

- Progressive familial intrahepatic cholestasis
- Dubin-Johnson syndrome, Rotor syndrome

<sup>a</sup>Young infants defined as infants younger than 6 months.

observed within the first 24 hours of life. Hemolysis is often seen in association with maternal-fetal blood type incompatibility. ABO and Rh incompatibility are the 2 most common types leading to hemolytic disease of the newborn. ABO incompatibility occurs in approximately 15% of all pregnancies but results in hemolytic disease in only 3% of newborns, with less than 0.1% of infants needing exchange transfusion. Hemolysis caused by ABO incompatibility is usually seen in newborns with blood type A or B born to blood type O mothers. Laboratory findings include a weakly positive direct Coombs test, high reticulocyte count, spherocytes on blood smear, and high levels of unconjugated bilirubin. Hemolytic disease in Rh incompatibility usually develops when an Rh-negative mother has become sensitized after exposure to Rh-positive fetal blood during a previous pregnancy. Rh incompatibility is less common and usually more severe than ABO incompatibility. In the United States, the

prevalence of the Rh-negative genotype is approximately 15% in whites, 5% in blacks, and less than 1% in Asians. Rh incompatibility occurs in approximately 1.06 per 1,000 live births. Affected infants usually develop jaundice in the first hours of life. Anemia and hepatosplenomegaly are common features. In severe cases, fetal hydrops from intrauterine hemolysis may be present at birth. Laboratory findings include a positive direct Coombs test, high reticulocyte count, anemia, and high unconjugated bilirubin levels. The prophylactic use of RhoGAM (anti-D gammaglobulin) in Rh-negative mothers has greatly decreased the incidence of this type of hemolytic disease of the newborn.

Other causes of hemolysis leading to unconjugated hyperbilirubinemia in the neonate include hemoglobinopathies such as  $\alpha$ -thalassemia, red blood cell enzyme defects, and neonatal polycythemia.  $\alpha$ -Thalassemia should be suspected in newborns with jaundice and a moderate hypochromic, microcytic, hemolytic anemia. Erythrocyte enzyme defects such as glucose-6-phosphate dehydrogenase (G6PD) or pyruvate kinase deficiency may cause hemolysis at any age. Neonatal polycythemia can cause an increase in bilirubin production as a result of an absolute increase in red blood cell mass. Unconjugated hyperbilirubinemia occurs in 2% to 22% of newborns with polycythemia. Cephalohematomas also can lead to an increased bilirubin production from rapid breakdown of red blood cells in the extravascular space.

#### Decreased Hepatocellular Uptake or Conjugation of Bilirubin

Drugs such as aspirin, cephalosporins, and sulfonamides can impair bilirubin transport by altering bilirubin-albumin binding. Rifampin has been demonstrated to competitively inhibit hepatocellular uptake of bilirubin. Unconjugated hyperbilirubinemia is associated with a decreased BUGT activity in conditions such as physiologic jaundice of the newborn and breast milk jaundice, and with a delayed maturation of BUGT in hypothyroidism.

Crigler-Najjar and Gilbert syndromes are 2 types of familial unconjugated hyperbilirubinemia caused by several mutations in the gene encoding for BUGT. *Crigler-Najjar syndrome* is a rare familial form of unconjugated hyperbilirubinemia caused by mutations in the gene encoding BUGT1, leading to either absent (type 1) or decreased (type 2) BUGT activity. Crigler-Najjar syndrome type 1 is an autosomal recessive disease, which presents with severe nonhemolytic jaundice in the first hours of life. Crigler-Najjar syndrome type 2 is an autosomal dominant disease. Jaundice is usually less severe in type 2 and may improve with phenobarbital treatment. *Gilbert syndrome* is rarely diagnosed in this age group, and is further discussed in the Jaundice in Older Infants and Children section.

#### Conjugated Hyperbilirubinemia

Conjugated hyperbilirubinemia, also known as *cholestatic jaundice*, is always pathologic. It can occur as a result of impaired bile formation by the hepatocyte or from obstruction to bile flow through the intrahepatic

or extrahepatic biliary system. Conditions associated with conjugated hyperbilirubinemia include primary hepatobiliary disorders, genetic or metabolic diseases, systemic infections, and drug toxicity. *Neonatal cholestasis* refers to infants younger than 3 months who have cholestatic jaundice regardless of the cause. With the availability of new diagnostic techniques, the number of patients with an identified specific cause has increased.

#### Systemic Illnesses

Congenital TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex) infections have been associated with conjugated hyperbilirubinemia. Infants with TORCH infections often have a low birth weight, hepatosplenomegaly, and cutaneous manifestations, as well as ophthalmologic and central nervous system involvement. Common laboratory findings include anemia, thrombocytopenia, increased transaminases, and cholestasis. Other infections, such as HIV and hepatitis B and C, may also be associated with conjugated hyperbilirubinemia in newborns or young infants. However, these infections have decreased with improved prenatal screening.

Patients with sepsis may develop jaundice and hepatocellular dysfunction. The most frequent bacterial organisms associated with conjugated hyperbilirubinemia in neonates are *Escherichia coli*, *Streptococcus* group B, and *Listeria monocytogenes*. Conjugated hyperbilirubinemia may also develop in newborns and young infants with urinary tract infections.

Critically ill patients, including young infants with no previous underlying liver disease, may develop jaundice with other signs of hepatic dysfunction, such as increased transaminases. Conditions such as cardiopulmonary arrest, shock, and severe metabolic acidosis may cause an acute ischemic insult to the liver resulting in hepatocyte necrosis. Affected patients will have a marked increase in serum transaminase levels and direct hyperbilirubinemia developing within 24 to 48 hours after the insult. In most cases, the liver function will normalize once the initial insult is corrected; rarely, patients may develop acute liver failure.

Liver disease associated with parenteral nutrition (PN) is often seen in patients who receive PN for more than 2 weeks. There is growing literature suggesting that soybean-based lipid emulsions are the major factor accounting for PN-associated liver disease. Recent data have demonstrated that using lipid emulsions based on fish oil can reverse or prevent PN cholestasis. Similar results have been achieved by limiting the soybean-based lipid emulsions to 1 g/kg/day or less.

#### Metabolic Disorders

Metabolic liver diseases usually manifest during early infancy and should always be considered in the differential diagnosis in a newborn or young infant with cholestasis, especially when associated with hypoglycemia, hyperammonemia, or lactic acidosis.

*Galactosemia* is an inborn error of galactose metabolism inherited as an autosomal recessive trait, with an estimated occurrence of 1 in 60,000. The classic transferase-deficiency galactosemia can affect multiple organs, including the liver, kidneys, brain,

eyes, intestines, and gonads. The hepatocellular damage in galactosemia is caused by accumulation of toxic metabolites of galactose-1-phosphate and galactitol in the liver. The clinical presentation varies from mild liver disease to fulminant liver failure in the neonatal period. Patients often have vomiting, diarrhea, and poor feeding. They can also present with *E coli* sepsis. Jaundice can also be found in patients with other inborn errors of carbohydrate metabolism, such as hereditary fructose intolerance and certain types of glycogen storage diseases. In these conditions, the onset of symptoms rarely occurs during early infancy.

*Neonatal hemochromatosis* is a rare and severe liver disease in newborns. The typical pathologic finding is excessive iron deposition in extrahepatic sites. It has been recently hypothesized that this condition is caused by maternal alloimmunity directed at the fetal liver. Infants with neonatal hemochromatosis usually experience intrauterine growth restriction and are born prematurely. In most cases, signs and symptoms of acute liver failure are present at birth or develop soon thereafter. The clinical presentation includes hypoglycemia, cholestatic jaundice, hypoalbuminemia, and profound coagulopathy. Transaminases can be slightly increased or even normal. Typical laboratory findings include increased ferritin and transferrin saturation and a relatively low transferrin level. Neonatal hemochromatosis should be strongly considered in all newborns with acute liver failure. Diagnosis can be aided by punch biopsy of the lip mucosa; the tissue sample is analyzed for iron deposition in the salivary glands. New treatment modalities include the use of intravenous immunoglobulin and exchange transfusions.

$\alpha_1$ -Antitrypsin deficiency is a relatively common genetic disorder, with the homozygous *PiZZ* genotype found in 1 in 1,600 to 2,000 live births. Only 10% of patients with  $\alpha_1$ -antitrypsin deficiency will develop signs and symptoms of liver disease. This disorder typically manifests in the first few months of life with jaundice, although the onset of liver disease can occur later in life. Liver injury results from the hepatotoxic effect of retained mutant  $\alpha_1$  *ATZZ* molecules in the endoplasmic reticulum of the hepatocyte.

*Tyrosinemia type 1*, also known as *hepatorenal tyrosinemia*, is a rare disorder that affects multiple organs, including the liver, kidneys, and peripheral nerves. The deficiency of fumarylacetoacetate hydrolase, an enzyme involved in tyrosine degradation, results in tissue accumulation of tyrosine and other intermediate metabolites. Clinical findings range from severe liver disease or acute liver failure in early infancy to chronic liver disease in older children. The striking laboratory finding is a markedly increased  $\alpha$ -fetoprotein level. Patients with this condition may develop hepatocellular carcinoma early in life. The presence of succinylacetone in urine or blood is pathognomonic for tyrosinemia. Early diagnosis is important because specific medical therapy will improve quality of life and delay disease progression.

Primary mitochondrial hepatopathies are caused by a variety of defects, including mitochondrial DNA depletion, respiratory chain defects, fatty acid oxidation defects, and mitochondrial membrane enzyme defects.

In addition to having signs and symptoms of liver disease, affected patients have neuromuscular problems. Marked lactic acidosis is a relatively common feature. Symptoms usually develop within the first few months of life.

### Obstructive Jaundice

*Extrahepatic biliary atresia* (EHBA) is an idiopathic, destructive, inflammatory process of both the extrahepatic and intrahepatic bile ducts. Affected infants typically develop jaundice and acholic stools at around 2 weeks of age; however, in early stages, the stools may still have bile pigment. Infants with cholestatic jaundice need prompt referral and evaluation for EHBA because the prognosis can be improved by early diagnosis and timely surgery. Abdominal sonography is a useful screening tool. The absence of gallbladder or the appearance of a *triangular cord sign* at the hilar region is suggestive of EHBA. However, the presence of a gallbladder on sonography does not exclude this condition. Abdominal sonography can also exclude other causes of cholestasis, such as choledochal cysts, gallstones, or biliary sludge. Liver biopsy is usually performed when evaluating patients with suspected EHBA, although the histologic findings are not always conclusive. The diagnosis is confirmed at the time of endoscopic retrograde cholangiopancreatography (ERCP) with cholangiogram or intraoperative cholangiogram. Once the diagnosis is made, a hepatoportoenterostomy or Kasai procedure is then performed in an effort to reestablish bile flow.

*Choledochal cysts* are rare congenital anomalies of the biliary tract characterized by varying degrees of cystic dilation of the biliary tree. Choledochal cysts may be detected at any age; 18% of cases are diagnosed during the first year of life. The classic presentation of jaundice, abdominal pain, and right epigastric mass is rarely observed in infants and young children.

*Alagille syndrome*, also known as *arteriohepatic dysplasia*, is inherited as an autosomal dominant condition with variable penetrance. It is characterized by paucity of the intrahepatic bile ducts, peripheral pulmonary stenosis, butterfly vertebrae, posterior embryotoxon, and peculiar facies. Jaundice and pruritus are often present as the main clinical features during infancy. Mutations in the Jagged 1 (*JAG1*) gene are identified in most patients. The diagnosis is confirmed by genetic testing.

### Isolated Bile Acid Metabolism Defects

Progressive familial intrahepatic cholestasis (PFIC) has been identified as a distinct group of conditions involving intrahepatic cholestasis from bile acid transport defects leading to impairment of bile excretion. Three distinct gene mutations have been identified, accounting for the 3 major subtypes of this condition, including *PFIC1*, *PFIC2*, and *PFIC3*. Genetic testing is available to detect these mutations. Affected patients often develop jaundice in the first few months of life. In addition, they may also have severe pruritus, growth failure, fat-soluble vitamin deficiency, abnormal coagulation profile, and increased serum bile acids. The disease usually progresses to cirrhosis and liver failure early in life.

## JAUNDICE IN OLDER INFANTS AND CHILDREN

A brief list of the differential diagnosis of jaundice in older infants and children is presented in Box 170-2. In this age group, jaundice is an unusual sign and may suggest a serious clinical condition.

### Unconjugated Hyperbilirubinemia

Unconjugated hyperbilirubinemia is seen in older infants and children usually associated with underlying hemolytic diseases such as sickle cell anemia, G6PD deficiency, or hereditary spherocytosis. Mild unconjugated hyperbilirubinemia may also result from nonhemolytic conditions such as *Gilbert syndrome*, a benign disorder that affects 7% of the general population. It is inherited as an autosomal dominant trait, although an autosomal recessive pattern has been described. An insertional mutation of the *UGT1A1* gene results in a reduced level of expression of the gene. Jaundice does not typically develop until after puberty and is usually seen during prolonged fasting or in association with acute viral illnesses. Patients usually have mild indirect hyperbilirubinemia with otherwise normal liver tests and no evidence of ongoing hemolysis.

### Conjugated Hyperbilirubinemia

#### Liver Disease

Jaundice can develop as a result of acute or chronic viral hepatitis, autoimmune hepatitis, and drug- or toxin-induced hepatic injury. Metabolic liver diseases are much less common in older children, with the exception of Wilson disease. Infiltrative malignancies can also cause jaundice at any age. The incidence of acute viral hepatitis A has decreased in the United States with the use of vaccination. Children younger than 5 years with acute hepatitis A infection tend to be anicteric. The disease rarely causes fulminant liver failure. Hepatitis E infection has been increasingly recognized recently and has a clinical course similar to that of hepatitis A. Hepatitis B or C infection is usually anicteric and chronic in children. Other viruses, such as Epstein-Barr virus, cytomegalovirus, adenovirus, and enterovirus, can also cause acute hepatitis, although jaundice is not always present.

*Autoimmune hepatitis* (AIH) is a progressive inflammatory condition of the liver of unknown etiology, which can progress to cirrhosis if not promptly diagnosed and treated. AIH should always be considered in the differential diagnosis in a patient with increased transaminases. Jaundice is present in more than one-half of patients with AIH. Hyperglobulinemia is often evident, and autoantibodies such as antinuclear antibody, anti-smooth muscle antibody, and anti-liver-kidney microsomal antibody may be positive or negative. A positive liver-kidney microsomal antibody categorizes the disease as AIH type 2, which may have a more fulminant course and can present as acute liver failure. AIH type 1 is more common, with onset likely before adolescence.

*Drug-induced liver injury* is initially suspected based on circumstantial evidence. It can be classified into 3 types—(1) hepatic, (2) cholestatic, or (3) mixed hepatic-cholestatic—according to different clinical features.

### BOX 170-2 Differential Diagnosis of Jaundice in Older Infants<sup>a</sup> and Children

#### UNCONJUGATED HYPERBILIRUBINEMIA

- Hemolysis: erythrocyte defects, erythrocyte enzyme defect (glucose-6-phosphate dehydrogenase), disseminated intravascular coagulopathy
- Gilbert syndrome

#### CONJUGATED HYPERBILIRUBINEMIA

##### Liver disease

- Viral hepatitis (hepatitis A, B, C, E)
- Hepatitis caused by other viruses (herpes simplex virus, Epstein-Barr virus, cytomegalovirus)
- Toxins and drugs (ethanol, acetaminophen, isoniazid, phenytoin)
- Autoimmune hepatitis
- Metabolic liver disease ( $\alpha_1$ -antitrypsin deficiency, tyrosinemia, Wilson disease, mitochondrial defects)
- Nonalcoholic fatty liver disease
- Acute liver damage: ischemia, hypoxia, acidosis
- Parenteral nutrition–associated liver disease
- Pregnancy related (acute fatty liver of pregnancy, preeclampsia)
- Malignancy

##### Obstruction of the biliary system

- Choledochal cyst
- Cholelithiasis or choledocholithiasis
- Cholecystitis
- Diseases of the bile ducts (primary sclerosing cholangitis, AIDS cholangiopathy)

##### Bilirubin metabolism or transport defects

- Progressive familial intrahepatic cholestasis
- Dubin-Johnson syndrome, Rotor syndrome

<sup>a</sup>Older infants defined as infants older than 6 months.

Cholestasis is more prominent when damage to bile duct epithelial cells occurs, resulting in an impaired bile flow. Cholestatic jaundice can be caused by many different drugs, including estrogen or oral contraceptive pills, erythromycin, cyclosporine, and haloperidol. Acetaminophen overdose can cause acute hepatitis with zone 3 hepatocyte necrosis. Most cases of drug-induced liver damage spontaneously resolve once the drug responsible for the injury is withdrawn.

*Wilson disease* is an autosomal recessive disorder of human copper metabolism, with clinical onset usually after 5 years of age. Mutations in the *ATP7B* gene lead to impaired biliary excretion of copper, which results in a progressive accumulation of copper in the liver and subsequently in other organs and tissues. Hemolytic anemia, Kayser-Fleischer rings in the eyes, and neuropsychiatric symptoms are classic features of the disease. Copper deposition in the liver can result in acute or chronic hepatitis, cirrhosis, or even fulminant liver failure with severe cholestatic jaundice.

### Biliary Obstruction

*Cholelithiasis* is the most common cause of biliary obstruction in children and is often associated with obesity, dyslipidemia, or an underlying hemolytic disease. Children usually present with vomiting and right upper quadrant abdominal pain, with or without jaundice. Primary sclerosing cholangitis is characterized by stenosis, dilation, and fibrosis involving the intrahepatic or extrahepatic biliary tree, or both. It is the most common form of chronic liver disease in children with inflammatory bowel disease. Cholestatic jaundice is seen in less than one-half of affected patients.

### Hepatic Bilirubin Transport Defects

Dubin-Johnson syndrome and Rotor syndrome are both inherited as autosomal recessive disorders. Dubin-Johnson syndrome is caused by mutations in the canalicular transporter gene, which result in an impaired secretion of conjugated bilirubin, whereas Rotor syndrome involves an impaired intracellular storage capacity of the liver for binding anions. In both syndromes, conjugated hyperbilirubinemia is present without abnormalities in other liver tests. The striking characteristic in Dubin-Johnson syndrome is a brown to black discoloration of the liver, which results from pigment deposition in the lysosomes. The liver histology is otherwise normal in both syndromes.

## EVALUATION

### History

A detailed history is essential when evaluating a patient with jaundice because the information obtained may help to identify the cause. Special attention should be paid to the presence of signs and symptoms, such as a viral prodrome, abdominal pain or distention, acholic stools, dark urine, or pruritus. In neonates, the prenatal and birth history may help identify potential risk factors. In older children, the patient's age at the time of onset of jaundice, associated signs and symptoms, and exposure to hepatotoxic agents are of paramount importance. A detailed family history should include information about the presence of persistent jaundice, chronic liver diseases, hemolysis, and metabolic diseases. Distinguishing among acute and chronic liver diseases, intrahepatic processes and extrahepatic biliary tract obstruction, or primary liver diseases and systemic diseases is the major goal at the time of the initial evaluation. This approach may guide the physician in selecting appropriate laboratory tests and imaging studies that can lead to a definitive diagnosis.

### Physical Examination

In general, patients with jaundice from unconjugated hyperbilirubinemia have bright-yellow skin, whereas patients with jaundice from conjugated hyperbilirubinemia have dark green-yellow skin. Patients should undergo a complete physical examination with special focus on general appearance, growth, and development; signs of cardiovascular dysfunction; neurologic signs; and organomegaly. The size and the character of the liver should be carefully determined. The newborn or infant liver is a large organ relative to body

size. In newborns, the mean liver span is 5.9 cm along the midclavicular line, calculated by measuring the distance between the percussed upper and palpated lower liver edges. The healthy infant's liver may be palpable and is typically less than 2 cm below the right costal margin. The consistency and character of the liver edge may help determine the nature of underlying liver disease. An enlarged liver resulting from an acute intrahepatic process is usually tender but soft. A cirrhotic liver may have a hard and irregular edge; however, its edge is not always palpable.

A thorough abdominal examination should be performed to identify the presence of an enlarged spleen or any other abdominal masses, areas of tenderness, and ascites, as well as the abdominal cutaneous venous pattern. The tip of the spleen can normally be palpated below the left costal margin in newborns and infants. Splenomegaly in a patient with underlying liver disease implies portal hypertension, especially in the presence of ascites and a prominent abdominal cutaneous venous pattern. Other physical findings may indicate a particular cause, such as xanthomas in primary biliary cirrhosis, Kayser-Fleischer rings in Wilson disease, and characteristic facial features and posterior embryotoxon in Alagille syndrome.

### Laboratory Tests

Initial laboratory studies include a complete blood cell count (CBC), liver tests, and a coagulation profile. Isolated hyperbilirubinemia with otherwise normal liver tests suggests the possibility of hemolytic disease or bilirubin metabolism defects. A CBC is useful in detecting hemolysis, indicated by the presence of anemia with fragmented red blood cells (schistocytes) and increased reticulocytes on the smear. Thrombocytopenia is typically seen in patients with portal hypertension and hypersplenism.

Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels are the most frequently used markers of hepatocellular injury. ALT is a more specific indicator of hepatocyte injury because AST also increases with hemolysis and myocardial or skeletal muscle injury. In general, a marked increase in AST and ALT occurs in severe viral hepatitis, acute toxin- or drug-induced hepatic necrosis, or ischemia. A mild increase of AST and ALT is seen in nonalcoholic fatty liver disease, chronic viral hepatitis, and drug toxicity. Declining AST and ALT levels usually indicate hepatocyte recovery. However, in the course of fulminant liver failure, if seen in association with a worsening liver synthetic function, falling AST and ALT levels may be an ominous sign of massive hepatic necrosis, with few viable hepatocytes remaining to further release these enzymes. AST and ALT levels are less useful in patients with chronic end-stage liver disease because they can be normal or only slightly increased in the presence of marked fibrosis of the liver.

Alkaline phosphatase and  $\gamma$ -glutamyltransferase (GGT) are useful markers for intrahepatic and extrahepatic cholestasis. In most hepatobiliary diseases, both alkaline phosphatase and GGT are increased. However, in progressive familial intrahepatic cholestasis (types 1 and 2), a normal or low GGT is

observed in the presence of a high alkaline phosphatase. Isolated increase of alkaline phosphatase may be seen in patients with nonhepatobiliary diseases such as bone disorders. Normal GGT values in newborns may be 5 to 8 times greater than those in adults.

Prothrombin time (PT) and albumin are used to evaluate hepatic synthetic function. An abnormal PT results from an impaired hepatic synthesis of coagulation factors I, II, V, VII, and X or deficiency of vitamin K (or both). Parenteral administration of vitamin K generally normalizes a prolonged PT in patients with vitamin K deficiency associated with cholestatic jaundice, but not in patients with hepatocellular disease. In acute liver injury, a markedly increased PT suggests the possibility of fulminant liver failure. Hypoalbuminemia may be seen in patients with acute and chronic liver diseases. In the early stages of acute liver injury, the serum albumin may not be a reliable indicator of hepatic synthetic function because it has a long half-life of approximately 21 days.

Based on the clinical information obtained and results of the initial laboratory tests, further evaluation including imaging studies may be warranted, including blood and urine cultures, viral serologic studies, toxin and drug screen, autoimmune markers,  $\alpha_1$ -antitrypsin phenotype, ceruloplasmin, urine succinyl acetone, and serum bile acids. In newborns or young infants with jaundice and abnormal liver tests, TORCH titers should also be obtained.

### Imaging Studies

Ultrasonography is the most useful initial imaging modality in the assessment of the intrahepatic and extrahepatic biliary system in patients with jaundice. This noninvasive study may help identify abnormalities such as biliary atresia, choledochal cyst, hepatic cystic lesions, and cholelithiasis. Computed tomographic scans may be preferred when general anatomic information of the hepatobiliary system is desired or a noncystic hepatic lesion is suspected. Nuclear scintigraphy is a useful study when considering the diagnosis of acute cholecystitis or chronic acalculous cholecystitis. Magnetic resonance cholangiopancreatography (MRCP) is a noninvasive study that identifies abnormalities of the intrahepatic and extrahepatic biliary system. ERCP provides similar information to that of the MRCP, but it allows the possibility of therapeutic interventions such as sphincterotomy, biliary stone extraction, or stent placement.

Liver biopsy provides information on the histology and architecture of the liver and has become an invaluable diagnostic tool in the evaluation of patients with liver disease; it is also helpful in assessing disease progression. Liver biopsy is most commonly performed in patients with persistently abnormal liver tests, especially when conventional laboratory and imaging studies do not lead to a specific diagnosis. The use of liver biopsy in the diagnosis of acute liver injury is limited because of the nonspecific histologic changes commonly found.

### MANAGEMENT

The treatment of newborns with unconjugated hyperbilirubinemia is based on the revised guideline

published by the American Academy of Pediatrics. This guideline provides a framework for detecting neonatal hyperbilirubinemia and preventing kernicterus in term and near-term newborn infants. It also emphasizes the importance of a systematic assessment of the risks of severe hyperbilirubinemia, close follow-up, and prompt intervention when necessary.

The management of patients with direct hyperbilirubinemia should focus on correcting the underlying cause, optimizing nutrition, and controlling pruritus. Malabsorption of fat and fat-soluble vitamins is commonly seen in patients with cholestasis because they have an impaired bile secretion. Unlike long-chain triglycerides, which require bile acid micelles for solubilization, medium-chain triglycerides (MCTs) are relatively water soluble and directly absorbed into the portal system. Therefore, a diet high in MCTs should be used to promote growth in children with chronic cholestasis. Formulas with a relatively high MCT concentration are often used in patients with cholestasis. Supplementation of fat-soluble vitamins A, D, E, and K is essential. Serum vitamin levels should be routinely followed to monitor adequate supplementation.

In the attempt to control cholestasis-associated pruritus, several different therapeutic agents have been used with very little success. Ursodeoxycholic acid has been shown to lower serum bile acid levels by increasing bile flow. Other agents, such as cholestyramine, a bile acid-binding resin, and rifampin, an antibiotic used in the treatment of tuberculosis, have also been used.

Liver transplantation in children is now an accepted therapy for many life-threatening liver diseases. Current survival rates for children after liver transplantation are 90% at 1 year and 85% at 3 years. EHBA is the most common indication for liver transplantation in children; other indications include  $\alpha_1$ -antitrypsin deficiency, fulminant liver failure, chronic hepatitis, metabolic liver disease, and cirrhosis of unknown origin. Early referral and transfer to a liver transplantation center are important to assure a good outcome.

#### WHEN TO REFER

- Unexplained jaundice
- Direct hyperbilirubinemia at any age
- Persistence of abnormal liver tests
- Hepatomegaly or splenomegaly

#### WHEN TO ADMIT

- Jaundice in an ill patient
- Feeding intolerance and dehydration
- Inpatient management of underlying conditions
- Impending acute liver failure

## Chapter 171

### JOINT PAIN

David M. Siegel, MD, MPH; Bethany Marston, MD

Pediatricians are often faced with clinical situations involving musculoskeletal aches and pains, and within this group of symptoms lies the subset of joint pain. In fact, 1 of every 6 to 10 pediatric outpatient visits includes a musculoskeletal complaint. Discomfort in a joint can result from a wide variety of causes, and the possibilities must be considered to allow appropriate evaluation and management. A systematic approach to patients who experience pain or swelling in 1 or more joints helps physicians arrive at an accurate diagnosis and course of therapy.

**DEFINITIONS**

Joint pain, or arthralgia, is the subjective experience of pain referable to a bony articulation. In a young child, this might be inferred from the patient's refusal to move an extremity. The term *arthralgia* should only be used if the discomfort originates in the joint itself; it is important to distinguish arthralgia from myalgia, or muscle pain, and from other types of pain that may involve the limbs but not the joints. The term *arthritis* should be used only when there is evidence of inflammation in the joint; findings of swelling, tenderness, warmth, or erythema should be demonstrable, along with pain with motion. In the joint, inflammation is also accompanied by stiffness or loss of motion. *Arthropathy* is a term that can be used to describe any disease of a joint, regardless of its cause.

**ETIOLOGY**

Inflammatory causes of musculoskeletal pain are typically subacute or chronic, and are characterized by swelling, loss of motion, and a subjective sense of stiffness that is often prolonged after periods of inactivity. A relatively rapid onset of joint symptoms in the setting of fever, rash, lymphadenopathy, or other systemic complaints should raise concern for an infectious process or a systemic inflammatory disease. Traumatic causes of musculoskeletal pain can typically be identified by the sudden onset of symptoms following a fall, a blow, or other injury. Repetitive stress injuries, hypermobility arthralgias, and other mechanical noninflammatory syndromes can be subacute or chronic in onset, but are characterized by exacerbation of pain and stiffness after activity or at the end of a vigorous day, rather than upon awakening or after periods of inactivity.

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis of joint pain should begin by determining whether the disease is inflammatory or noninflammatory. Inflammatory joint disease can result from rheumatic or nonrheumatic causes. Noninflammatory diseases may result from trauma, repetitive stress, congenital or developmental anomalies, or other mechanical causes.

**Rheumatic Diseases**

The most common rheumatic disease of childhood is juvenile idiopathic arthritis (JIA), previously referred to as *juvenile rheumatoid arthritis*, which occurs in up to 1 in 1,000 children worldwide. Onset can be from the second year of life through late adolescence. The oligoarticular subtype is characterized by involvement of 4 or fewer joints, typically large joints with asymmetric distribution. This subtype has a good long-term prognosis, but can cause growth abnormalities, and especially in patients with a positive antinuclear antibody it carries an increased risk of eye involvement with iridocyclitis. When more than 4 joints are involved, JIA is subtyped as polyarticular, and this form is more likely to involve small as well as larger joints. A subset of patients with polyarticular JIA have serum IgM rheumatoid factor and typically more symmetric joint disease. Systemic onset juvenile arthritis

(sometimes called *Still disease*) is marked by high, spiking fevers; an evanescent, salmon-pink, maculopapular rash; lymph node, spleen, and liver enlargement; anemia; leukocytosis; and other laboratory evidence of pronounced inflammation. Arthritis may not be present at the onset of systemic findings, but should be present for 6 weeks or longer to establish the diagnosis of any form of JIA. Evaluation and management of JIA depends on the subtype present.

Juvenile forms of ankylosing spondylitis or spondyloarthropathy can start with involvement in the large joints of the lower extremities or in the entheses (insertion of a tendon or ligament into a bone); at onset, there may be no axial disease. Small joint involvement is often asymmetric when present, and dactylitis (sausage digits) can occur if several joints and intervening soft tissues in a single finger or toe are swollen. The classic presentation of ankylosing spondylitis includes sacroiliac involvement in late adolescence, and further axial disease can progress in adulthood. Severe disease leads to the radiographic finding of *bamboo spine*, which is caused by diffuse paravertebral fusions resulting in very limited back and neck movement. The human leukocyte antigen (HLA)-B27 is seen in about 90% of patients with ankylosing spondylitis. Spondylarthropathies are more common in boys than girls, unlike many other forms of juvenile arthritis. A similar pattern of asymmetric large joint and sacroiliac disease can be seen in patients with inflammatory bowel disease. Children with psoriasis, or with a first degree relative with psoriasis, may also have a similar presentation, with a predisposition for large joints, sacroiliac disease, and occasionally dactylitis.

Several other systemic inflammatory diseases may cause or be associated with arthritis. Systemic lupus erythematosus, more common in girls than boys and infrequently seen before adolescence, is a multisystem disease that can involve almost any organ in the body. Arthralgias and sometimes arthritis are not uncommon, and may be the presenting symptom. Juvenile dermatomyositis is characterized more by skin rashes and muscle inflammation and weakness than joint disease, but can also be accompanied by joint pain or swelling in some cases. Sjögren syndrome, scleroderma, and mixed connective tissue disease are other connective tissue diseases occasionally seen in children that can cause joint symptoms. Systemic autoimmune inflammatory syndromes, often referred to as *periodic fever syndromes*, including familial Mediterranean fever, tumor necrosis factor receptor-associated periodic syndrome, hyperimmunoglobulin D syndrome, and cryopyrinopathies, are genetic diseases that may be associated with arthritis in addition to recurrent fevers. Kawasaki disease and Henoch-Schönlein purpura, along with other types of vasculitis, are also systemic inflammatory diseases that can cause arthritis. Many other inflammatory conditions cause arthritis in adults, including sarcoidosis and crystalline arthritis, but these are quite rare in children.

### Infectious and Postinfectious Arthritis

Acute bacterial infection of the joint, or *septic arthritis*, is foremost among this group and represents a medical

emergency. The usual manifestation is the rapid onset of pain in a joint, typically accompanied by fever. The joint itself is red, warm, swollen, and exquisitely tender to palpation or with movement. This clinical situation demands immediate arthrocentesis for diagnosis and therapy. Analysis of the fluid for appearance (opaque), viscosity (usually low), mucin clot (friable), cell count ( $>100,000$  white blood cells/mm<sup>3</sup> with at least 80% polymorphonuclear cells), glucose (usually low, much less than serum), and protein (high) helps establish the diagnosis. Most important, a portion of the fluid must be Gram stained to assess for bacterial organisms. Cultures can direct definitive antimicrobial therapy. In the past, for a child younger than 4 years, *Haemophilus influenzae* was the most commonly responsible organism; but with the institution of regular immunization, these bacteria are no longer a major consideration in septic arthritis. *Staphylococcus aureus* and *Streptococcus* species now are more likely to be the causative organisms. In addition to joint fluid cultures, blood cultures may also yield growth of the organism, occasionally in the absence of a positive joint fluid culture.

*Osteomyelitis* is an acute infection of the bone. However, when one of the long bones next to a joint (eg, the distal femur and knee) is infected, the patient may describe pain in the joint, and a sterile effusion may even be present. Although unusual, the bacterial infection can directly invade the adjacent joint space from the bone, particularly in young children.

Systemic bacterial infections, notably those caused by *Neisseria meningitidis* and *Neisseria gonorrhoeae*, also can produce arthritis, although the organism is usually not isolated from the joint in these cases. After joint aspiration and establishment of at least a strong suspicion of a purulent arthritis, the child should be hospitalized and appropriate intravenous antibiotic therapy initiated. Prompt, aggressive therapy usually brings about recovery without adverse side effects, although some foci, such as the hip joint, can remain persistent problems. Because of the tenuous blood supply to the femoral capital epiphysis, purulent arthritis of the hip can lead to chronic problems despite timely intervention.

Diskitis, a disorder characterized by back pain and tenderness over the spinous process contiguous to the involved disk space, causes joint pain, sometimes with low-grade fever, but often with none. *Staphylococcus aureus* has been isolated from the blood and disk space in some instances, but often no culture-proven cause can be found. The presentation can involve sensory and motor complications resulting from nerve root impingement, and an epidural abscess must be considered in the differential diagnosis.

*Borrelia burgdorferi* is a tick-borne spirochete responsible for Lyme disease. The syndrome, which was first described in Old Lyme, Connecticut, is characterized by an initial tick bite that often (but not always) causes a large, circular, spreading, erythematous lesion known as *erythema migrans*. Meningoencephalitis, neuritis, and carditis also may occur. The arthritis occurs later in the course as recurrent attacks of inflammation of the large joints (85%–90% of cases involve the knee), with each recurrence usually lasting

no more than 1 or 2 weeks. Occasionally, symptoms may persist for several months, and chronic, persistent arthritis of the knee has been reported. A short course of high-dose amoxicillin therapy seems to shorten the course of the rash and perhaps attenuates the arthritis, and nonsteroidal anti-inflammatory drug (NSAID) therapy relieves the symptoms. Specific antibiotic regimens are suggested for different stages of disease and ages of patients. Although a vaccine against *B burgdorferi* was developed and distributed, it was taken off the market in 2002 and is no longer available.

In addition to bacteria, other infectious organisms can cause joint disease. Viruses, including rubella, mumps, varicella, parvovirus, adenovirus, the Epstein-Barr virus, and HIV, all can affect synovial tissue. Manifestations of the viral syndrome (rash, fever, mucous membrane involvement) usually precede joint involvement. Infectious hepatitis, on the other hand, can cause arthritis before overt hepatic involvement. Rubella immunization is associated with arthralgia and arthritis in as many as 3% of children who receive the vaccine, although rarely, if ever, with any sequelae. Other less common infections that can involve the joints include brucellosis, leptospirosis, tularemia, Rocky Mountain spotted fever, and rat-bite fever. Mycobacteria can cause arthritis, as can various fungal agents, particularly in immunocompromised individuals.

Reactive arthritis, previously referred to as *Reiter syndrome*—a triad of urethritis, conjunctivitis, and arthritis—may appear in children and adolescents. In children, it is often triggered by an episode of enteritis. Reactive arthritis is more common in boys than in girls, and making the diagnosis depends on excluding direct infectious causes of the inflammation. The arthritis predominantly occurs in large joints; again, it is often but not exclusively associated with the HLA-B27 class 1 major histocompatibility locus. The disorder is treated initially with anti-inflammatory drugs. Most children recover within a few months, although some follow a more chronic and relapsing course and can progress to ankylosing spondylitis. Transient synovitis of the hip, previously called *toxic synovitis*, also can cause arthralgia, arthritis, or both. This generally occurs in preschool or young school-aged children, and has a good prognosis. Etiology is unclear, but it may be viral or postviral in nature.

Acute rheumatic fever is less common than it once was, but is still an important consideration in a child with the acute onset of arthritis or arthralgia. This follows an infection with group A streptococcus, usually pharyngitis, usually and typically by about 2 or 3 weeks. Diagnosis is made using the Jones criteria, which include migratory arthritis or arthralgias as well as fever, carditis, rash (erythema marginatum), central nervous system involvement, subcutaneous nodules, elevated acute phase reactants and prolonged PR interval. A distinct condition called *poststreptococcal reactive arthritis* may occur after a streptococcal infection, in the absence of other findings. The arthritis may be more severe, and this may occur sooner after the preceding illness than is the case with rheumatic fever.

### Noninflammatory Causes of Joint Pain

Trauma causing fractures, dislocations, cartilage, ligamentous, or tendon injury, or other soft tissue damage are common in children and can cause joint pain, depending on the location of the injury. A careful history can usually provide information about the mechanism of the event. Physical abuse (non-accidental trauma) should be considered whenever signs of trauma are evident, and accidents that represent neglect on the part of parents or guardians need to be recognized and pursued. Any suspicious history or circumstance demands complete investigation.

Other more chronic mechanical stressors can lead to subacute arthralgia. Patellofemoral pain syndrome, also called *chondromalacia patellae*, is a common cause of anterior knee pain in children and adolescents, and is often bilateral. Knee pain is usually related to activity, and the child may report symptoms of “locking” with prolonged sitting, or “giving way” with extended standing. Exercises that strengthen the quadriceps femoris and adductor muscles can produce marked improvement. Repetitive activities can lead to chronic tendonitis or bursitis in periarticular areas, and are common in athletes, dancers, musicians, and other children who practice or perform repetitive movements. Stress fractures are uncommon in children but should be considered in an athlete with chronic bone or joint pain. Some injuries are specific to a developmental stage, such as Osgood-Schlatter disease, Sever disease, and other forms of apophysitis. These occur only in skeletally immature individuals who have either a repetitive or acute injury to the apophysis, which is a secondary ossification center to which a tendon attaches, and which is the weakest point of the biomechanical unit. These are treated by activity modification, rehabilitation, and analgesia as needed. Slipped capital femoral epiphysis is another condition seen only in skeletally immature children, in which the capital femoral epiphysis is displaced from the femoral neck. This may manifest as hip or sometimes thigh or knee pain, and is seen typically in overweight adolescents, and is diagnosed by imaging.

Some children experience arthralgias in the lower extremities, termed *growing pains*, which tend to be worse at night. These are not associated with warmth, swelling, or limitation of movement of the affected joints. Imaging will be normal. These children rarely have pain in the mornings, and have normal daytime activities. Symptoms can often be alleviated with a bedtime dose of NSAID or acetaminophen. Children with hypermobility syndrome often have a similar pattern of pain, worse after activity and improved by rest. Children with this disorder have increased joint laxity, and can be diagnosed by the presence of at least 3 of the following signs: hyperflexion of the wrist, bringing the thumb in contact with the volar surface of the forearm; hyperextension of the fingers to parallel with the forearm; hyperextension of the elbow to at least  $-10$  degrees; hyperextension of the knee to at least  $-10$  degrees; and hyperflexion of the spine such that with forward flexion, the palms can be placed flat on the ground with the feet together and without flexing the knees. Some genetic disorders of connective tissue, including Marfan syndrome and

Ehlers-Danlos syndrome, can cause pronounced hypermobility.

In an adolescent with chronic diffuse pain and fatigue without evidence of rheumatic disease on examination or laboratory studies, juvenile primary fibromyalgia syndrome should be considered. Multiple sets of diagnostic criteria have been published, but these generally include widespread pain for several months, presence of specific tender points on examination, and the presence of severe fatigue and nonrestorative sleep. These children often also have headaches, depression or anxiety, a sense of cognitive impairment, numbness or tingling or stiffness in the limbs, irritable bowel symptoms, or other complaints. Treatment should be multidisciplinary, and should include patient and family education, exercise, and psychological interventions such as cognitive behavioral therapy. Some patients benefit from medications including non-narcotic analgesics, low-dose tricyclic antidepressants, other antidepressants, and  $\gamma$ -aminobutyric acid agonists such as gabapentin or pregabalin.

Children who present with localized limb pain, sometimes after an injury but out of proportion to examination findings, may have complex regional pain syndrome (CRPS). The affected area should also demonstrate some evidence of autonomic dysfunction such as localized edema, increased sweating, or change in temperature or color. As with juvenile fibromyalgia, onset is most common in adolescent girls, and concurrent sleep disruption and psychological conditions are also common. Treatment consists of aggressive physical and occupational therapy, psychological and behavioral therapies, and sometimes pharmacotherapy or localized interventions such as nerve blocks.

### Other Causes

Hematologic disorders that have articular manifestations include hemophilia and sickle cell disease. In the latter disorder, the hand-foot syndrome type of vaso-occlusive crisis is a common initial presentation in children between 1 and 4 years of age.

Bone pain can also occur in patients with osteoid osteomas, which are benign bone tumors most often seen in older children and teens. Pigmented villonodular synovitis is a benign neoplasm of the synovium which can present with joint pain and swelling. Leukemia is the most common malignant condition to present with bone or joint pain, although lymphoma, neuroblastoma, and Ewing and other sarcomas can also cause these symptoms.

### EVALUATION

A complete history is indispensable in the initial assessment of a child with joint pain. The physical examination can then substantiate or alleviate suspicions raised during the interview. Distinguishing among arthritis, arthralgia, periarticular pain, and myalgia is essential. Further testing, including appropriate imaging, can confirm or further clarify the nature of bony or soft tissue abnormalities suspected based on the history and examination findings. In

some cases, the diagnosis can be reinforced by laboratory testing. Markers of inflammation, including erythrocyte sedimentation rate, C-reactive protein, and others, are often abnormal in inflammatory conditions. In some cases, appropriate specific tests or cultures can confirm a specific rheumatic or infectious diagnosis.

### TREATMENT

Management of joint pain that is secondary to an inflammatory arthritis focuses on subduing inflammation and preserving normal range of motion, strength, and function. NSAIDs are often used as initial therapy. In patients with oligoarticular disease, especially those with a single persistently active joint, intraarticular corticosteroids can be effective. Systemic corticosteroids occasionally have a place in therapy of other JIA subtypes, although they are used much less often than in the past, and with a goal of limited duration. Methotrexate has come to play a central role in the medical management of children with JIA and some other inflammatory conditions who require therapy beyond NSAIDs. Other immunomodulatory agents, such as sulfasalazine, leflunomide, and hydroxychloroquine may also be used in some patients. Many patients who have resistant joint inflammation or high-risk phenotypes benefit from biologic agents, including antitumor necrosis factor alpha agents, IL-1 or IL-6 antagonists, and others.

Any child with a bacterial infection of the joint space or bone should be promptly identified and treated with intravenous antibiotics. Other infectious causes of arthritis may also require treatment, such as those caused by Lyme disease or *Neisseria* infection. Others, such as parvovirus, will generally resolve spontaneously, so treatment is supportive.

In patients with joint pain resulting from trauma, therapy includes rest, ice, NSAIDs, or other analgesics, though any unstable injury should be promptly evaluated by an orthopedist to determine the need for external or surgical stabilization. There may also be a role for surgical treatment of longstanding joint damage resulting from chronic or severe inflammatory arthritis or mechanical derangements, and sometimes surgical interventions are necessary for establishing a clear diagnosis, as in synovial biopsy for atypical infections or bone biopsy for osteomyelitis.

After arriving at a diagnosis and plan of therapy, the physician must also offer management for the psychological aspects of joint disease. In children with ongoing joint problems, issues related to chronic pediatric disease must be addressed. The child may be unable to keep up with peers in physical activity and may be faced with having to make many health care visits, resulting in school absences. Many physicians think that environmental stress, in addition to the stress caused by the disease, can exacerbate various chronic conditions, and such may occur in children with JIA.

Children faced with hospitalization for an acute problem, such as septic arthritis, are exposed to all the complications of being taken out of their family and school environment, as well as having to deal with an

institutional setting. Children with ongoing joint disease, even those with only a mild disability, should be provided with the services of a specialized social worker, counselor, or psychologist. Family resources (both emotional and financial) need to be assessed and support provided when needed. Discussion groups or support groups composed of these children and their families can be helpful because they offer an opportunity to compare experiences and coping mechanisms. Attention to the physical dimension alone does not provide adequate care in these diseases. A functionally minor disability can cause major problems of body image and feelings of lack of independence that must be dealt with appropriately. As with other chronic physical disorders of childhood and adolescence, long-term psychosocial sequelae also may develop.

### WHEN TO REFER

- Orthopaedics
  - Fracture
  - Ligamentous or cartilage injury to joint
  - Continuous pain in a joint with deformity
- Rheumatology
  - Suspicion of juvenile arthritis or other rheumatologic disorder
- Infectious diseases
  - Septic arthritis
  - Lyme disease; other spirochetal infection
  - Osteomyelitis
- Hematology
  - Sickle cell disease
  - Hemophilia
- Gastroenterology
  - Joint symptoms associated with inflammatory bowel disease
- Occupational or physical therapy
  - Joint disease complicated by contractures, weakness, poor function
  - Hypermobility syndrome
  - Pain amplification syndromes (eg, fibromyalgia, CRPS)
- Mental health
  - Suspicion of somatization or conversion disorder

### WHEN TO ADMIT

- Fracture requiring open fixation or traction
- Systemic onset juvenile arthritis with macrophage activation syndrome
- Septic arthritis
- Osteomyelitis
- Severe sickle cell pain crisis
- Admit to rehabilitation if inadequate response to outpatient occupational or physical therapy

### TOOLS FOR PRACTICE

#### Engaging Patient and Family

- *What is a Pediatric Rheumatologist?* (fact sheet), American Academy of Pediatrics ([www.healthychildren.org/English/family-life/health-management/pediatric-specialists/Pages/What-is-a-Pediatric-Rheumatologist.aspx](http://www.healthychildren.org/English/family-life/health-management/pediatric-specialists/Pages/What-is-a-Pediatric-Rheumatologist.aspx))

#### Medical Decision Support

- *Red Book: 2015 Report of the Committee on Infectious Diseases*, 30th ed (book), American Academy of Pediatrics ([shop.aap.org](http://shop.aap.org))

## Chapter 172

## LEARNING DIFFICULTY

Barbara L. Frankowski, MD, MPH

### BACKGROUND AND SIGNIFICANCE

Learning difficulties can occur at any age and for a variety of reasons. They invariably cause frustration for the child or adolescent, which can lead to or compound behavior problems and emotional distress. The effects of learning difficulties, whatever their cause, can be profound, with economic and emotional consequences far into adult life. Children who do not receive timely intervention are at risk not only for academic failure, but also for the psychosocial morbidities that accompany limited academic achievement, such as substance abuse and juvenile delinquency. Some children with learning difficulties are among the 7% of US 15- through 24-year-olds who drop out of school, leading to chronic unemployment, poverty, and higher risk of health problems throughout adulthood. The drop-out rate is higher among minority populations of black non-Hispanics (8%) and Hispanics (22.5%) than white children. Clearly, learning difficulties are an important concern for primary care physicians providing services to children and adolescents.

### PRIMARY CARE PHYSICIAN'S ROLE

It is the primary care physician's role to recognize that a child is experiencing difficulty in learning, to help the family sort out the cause of the child's learning difficulties, to identify referral sources for psychological and educational assessment, to ensure that the child receives the educational resources he or she needs and is entitled to, to address any medical or mental health problems that may be associated with the child's learning difficulties, and to guide the family in advocating and providing a supportive environment for the child.

## RECOGNITION OF CHILDREN WITH LEARNING DIFFICULTIES

The primary care physician has opportunities at routine health supervision visits to elicit parental concerns, to monitor children's developmental progress and functioning, and to screen for developmental delays and symptoms of social and emotional problems. The physician may also receive referrals from childcare or school personnel who have observed that the child has difficulty learning compared with his or her peers or is experiencing behavioral problems in the classroom. There may be a family history of learning problems, compounding concerns about the child's progress in learning. Box 172-1 and Table 172-1 for signs and symptoms that a child is experiencing learning difficulties.

### BOX 172-1 Symptoms and Clinical Findings Suggesting Learning Difficulties

#### INDICATIONS FROM YOUTH'S OR PARENT'S HISTORY

- Child has experienced a delay in language development or has difficulty understanding language despite normal hearing and vision.
- Child has difficulty following directions.
- Child has difficulty learning letters, numbers, and colors.
- Child has struggled to read, grasp math concepts, or write in comparison with her peers.
- Letter reversals (b/d), inversions (m/w), transpositions (felt/left), substitutions (house/home), or confusion of arithmetic signs persist past peers.
- Child avoids reading aloud, writing, or homework.
- Child or parent is frustrated with the child's academic performance.
- Parent perceives child is "lazy" in school.
- Child is perceived as an "underachiever."
- Classroom behavior or inattention has become a problem.
- Other family members have experienced learning difficulties or did not complete high school.

**Table 172-1** Findings Suggesting Learning Difficulty

#### MEASUREMENT SCORE

End-of-grade test scores or achievement test scores	Percentiles are low ( $\leq 15\%$ ) or markedly scattered, or the child is performing considerably less well than would be expected for his or her intelligence.
Report cards	Grades are low or markedly scattered.
Intelligence tests	Percentiles are within the normal range or significantly higher than measures of academic achievement.

## CAUSES OF LEARNING DIFFICULTIES

### Lack of School Readiness

Some young children experience difficulties in learning because they are not yet ready for the school experience, socially, emotionally, or physically; because they do not have language and literacy skills comparable with their peers; or because their family or culture does not value their education. Box 172-2 outlines the specific traits a child should ideally possess in order to be ready for school, and Box 172-3 identifies key family and community supports for preparing a child for school.

Finally, many schools are not prepared to educate children with the full range of abilities and disabilities. Measurement of children's readiness for kindergarten should be used to assess the effectiveness of community-based programs and to prepare schools to meet the child's ongoing needs, rather than to exclude or delay children from their formal educational experience. Box 172-4 highlights key elements of schools that are ready for children.

### BOX 172-2 Traits for School Readiness

- Physical well-being and motor development: good health status and alertness; any physical disabilities identified and accommodated
- Social and emotional development: turn-taking, cooperation, empathy, and the ability to express his or her own emotions
- Approaches to learning: enthusiasm, curiosity, family and cultural values supportive of learning
- Language development: skills in understanding and speaking the language spoken in the classroom; adequate vocabulary and other literacy skills, including print awareness, story sense, and writing and drawing processes
- General knowledge and cognition: sound-letter association, awareness of spatial relations, and number concepts

### BOX 172-3 Preparing the Child for School: Key Elements

- At least a high school education or equivalent for parents
- High-quality prenatal health care for the mother
- Optimal nutrition for mother and child
- Comprehensive health care for the child
- Daily physical activity
- Daily time with parent in learning activities (eg, reading, conversation, family meals)
- Access to high-quality preschool for children in impoverished environments
- Access to programs for children and parents who speak English as a second language

### BOX 172-4 Preparing the School for the Child: Key Elements

- High-quality preschools for children in impoverished environments
- Programs and teacher training for children of all ability levels
- Preschool screening of children aimed at measuring the outcome of their preschool programs and at identifying and addressing students' needs (not at excluding children or delaying their school entry)

### Medical, Mental Health, and Developmental Problems

Learning difficulties may also be caused by cognitive limitations, a language or learning disorder; vision or hearing impairment; behavioral and emotional problems; a chronic disease that affects the child's concentration, interpersonal relationships, or school attendance; sleep deprivation; or medication affecting concentration or alertness. See Table 172-2 for a listing of problems that can cause or co-occur with learning difficulties.

### Learning Disabilities

Rarely diagnosed before a child enters school, learning disabilities (LDs) represent a broad array of specific learning challenges that significantly impede a child's ability to perform at the expected grade level. They generally occur in the context of normal sensory functioning and otherwise normal cognitive capabilities and, by definition, are not the result of a primary emotional disorder or lack of opportunity (although frustration and low self-esteem associated with LDs may contribute to development of problems such as anxiety, depression, or oppositionality). Learning disabilities are clearly familial, with genetics contributing substantially to a child's risk. It is estimated that between 5% and 17.5% of individuals meet diagnostic criteria for LDs and approximately 2 million US schoolchildren aged 6 to 11 years are affected. Eighty percent of those identified have dyslexia or a reading disorder.

### ASSESSMENT OF CHILDREN WITH LEARNING DIFFICULTIES

Assessment begins by differentiating the child's symptoms from normal behavior. Children learn at different rates. Typically developing children younger than 7 years may reverse and transpose letters and experience some frustration with new learning tasks, particularly if the child has had limited preschool experience or other children in the classroom have had more exposure to formal school experiences. Many children will have 1 or more of the symptoms in Box 172-1 from time to time. Children who have missed school for an illness, changed schools, or experienced a significant loss may experience transient problems with school functioning. Some parents have unrealistic expectations, based on their own learning experiences or that of older siblings or children of friends.

It is important to explore sources of stress in the family, school, or community, as any of these can cause inattentiveness and distraction in the child.

A full physical and psychosocial assessment of the child will serve to identify conditions that can cause or co-occur with learning difficulties (Table 172-2).

Two categories of medical risk deserve special attention: prematurity and cyanotic congenital heart disease. Premature infants are at significantly higher risk for global developmental delays and for LDs. In particular, children born at less than 32 weeks' gestation or who experience perinatal and postnatal complications such as prolonged ventilation, intracranial hemorrhage, sepsis, seizures, prolonged acidosis, or hypoglycemia are at higher risk for neurodevelopmental sequelae. Similarly, children surviving severe congenital cardiac anomalies are at high risk for LDs. Several genetic disorders have been linked to risk for various forms of LD. In particular, children with Klinefelter syndrome, Turner syndrome, velocardiofacial syndrome, and spina bifida with shunted hydrocephalus have all been shown to be at significant risk for LDs. When 1 of these risk factors is identified, the physician should have a low threshold to refer for psychological and educational assessment.

Adolescents who present with learning difficulties are a particular challenge for the primary care physician. An adolescent who has been progressing normally with academics may suddenly develop learning difficulties. It is possible that the adolescent may have a mild learning disability for which he or she has compensated in lower grades, but which is now causing difficulty in meeting the more rigorous demands of middle or high school. Together or separately, the adolescent may have mild attentional problems that have not required any special intervention up until this point. However, it is also possible that the adolescent has other problems causing or contributing to learning difficulties, such as inadequate amounts of sleep, poor nutrition, inadequate physical activity, anxiety, depression, or substance abuse. The adolescent could also, or alternatively, be struggling with issues of sexual orientation or bullying that cause stress in the school environment. It is important to consider all these possibilities when assessing an adolescent with learning difficulties.

To further the assessment of any child or adolescent with learning difficulties, the physician can communicate with school personnel (eg, guidance counselor, classroom teacher, school psychologist) to request data and observations such as the following:

- **Intelligence testing:** School personnel may be willing to administer a cognitive screening test or, if there are apparent discrepancies between intelligence and academic achievement, a full battery of psychological tests.
- **Achievement testing:** School personnel can provide a screening test or reports of achievement or end-of-grade tests.
- **Full psychoeducational evaluation:** School psychologist or community psychologist may provide, by referral.
- **School placement and special services.**
- **Individualized Educational Program (IEP) or 504 plan,** if in place.

**Table 172-2** Conditions That May Cause Poor School Performance or Co-occur With Learning Difficulties

CONDITION	RATIONALE
Hearing or vision problems Sleep deprivation	All children who are experiencing learning difficulties should be screened for sensory deficits. Sleep problems can cause inattention and irritability and contribute to poor school performance; conversely, poor school performance and homework struggles may contribute to difficulty sleeping.
Developmental problems	Children with overall intellectual or social limitations will learn more slowly than their age-mates. Children with low achievement and low intellectual levels often have the same problems as children with learning disabilities.
Attention-deficit/hyperactivity disorder (ADHD)	Children who are inattentive or impulsive may manifest poor academic performance. They may have problems with getting the work completed and turned in, rather than skill deficits. Conversely, children experiencing academic difficulties may seem restless and inattentive. See Chapter 168, Inattention and Impulsivity.
Exposure to adverse childhood experiences (ACE)	Children who have experienced or witnessed trauma, violence, a natural disaster, separation from a parent, parental divorce or separation, parental substance use, neglect, or physical, emotional, or sexual abuse are at high risk of developing emotional difficulties such as adjustment disorder or post-traumatic stress disorder (PTSD). Children with PTSD can manifest poor concentration, memory problems, school refusal, and academic decline. These children may also manifest other forms of anxiety. Physicians may want to consider speaking separately and confidentially with the youth and parents to explore this possibility. Parents are often unaware of exposures that children may have had at school or in the community. There may be major traumas in the family (eg, serious illness in a parent, maltreatment of the child, death or incarceration of a loved one) that are similarly not discussed or disclosed. The 3 hallmark symptom clusters of PTSD are reexperiencing, avoidance of memories or situations that recall the trauma, and hypervigilance (ie, increased worry about safety, startling or anxiousness at unexpected sounds or events). See also Chapter 129, Anxiety.
Anxiety	Anxious children may experience difficulty concentrating and perform poorly on tests. See Chapter 129, Anxiety.
Bereavement	Most children will experience the death of a family member or friend sometime in their childhood. Other losses may also trigger grief responses—separation or divorce of parents, relocation, change of school, deployment of a parent in military service, breakup with a girlfriend or boyfriend, or remarriage of parent. Such losses are traumatic. They may result in such symptoms as sadness, anxiety, difficulty concentrating, poor impulse control, or academic decline immediately following the loss and in some instances, more persistently. See also Chapter 137, Depression, and the discussion of PTSD in Chapter 129, Anxiety.
Depression	Depression may cause a decline in school performance, result from poor school performance, or simply coexist with learning disabilities. Marked sleep disturbance, disturbed appetite, low mood, or tearfulness could indicate that a child (or more commonly, an adolescent) is depressed. See Chapter 137, Depression.
Physical illness	Medical issues that may have an effect on school performance include all illnesses that may interfere with the child's attendance. Some illnesses (or symptoms caused by the illnesses) can affect attention in the classroom (eg, hypo- or hyperthyroidism, neurologic disorders, post-traumatic brain injury, undiagnosed diabetes), as can side effects of medications such as bronchodilators or anticonvulsants.
Substance use	Children frustrated with their school performance may use substances such as alcohol, nicotine, or other drugs to alleviate their frustrations, or self-medicate with caffeine or cocaine. Conversely, children using substances may manifest inattention, impulsivity, and deteriorating school performance. See Chapter 198, Substance Use: Initial Approach in Primary Care.
Conduct or oppositional disorders	These disorders may cause poor academic performance, and frustration with poor academic performance can exacerbate conduct or oppositional problems. See Chapter 139, Disruptive Behavior and Aggression.
Autism spectrum disorders including high-functioning autism, which was formerly known as pervasive development disorder, and Asperger syndrome	Children who have these difficulties also have problems with social relatedness (eg, poor eye contact, preference for solitary activities, language [often stilted], and range of interests [persistent and intense interest in a particular activity or subject]). They often will have very rigid expectations for routine and become anxious or angry if these expectations are not met. As such, these children may manifest difficulties in the classroom and many of the symptoms associated with learning disorders.

- **History of academic progress, behavior and discipline, and peer interactions.**

Use of additional instruments such as the Vanderbilt ADHD Rating Scale (see Tools for Practice) and general psychosocial screens [Pediatric Symptom Checklist (PSC)-35, PSC-17, Strengths and Difficulties Questionnaire (SDQ)] can be used to identify children who may have psychosocial problems contributing to their learning difficulties.

## PLAN OF CARE FOR CHILDREN WITH LEARNING DIFFICULTIES

The care of a child experiencing learning difficulties can begin in the primary care setting from the time symptoms are recognized, even if the child's problems do not rise to the level of a disorder or referral to the school or to a mental health specialist is ultimately part of the care plan.

### Engage Child and Family in Care

Without engagement, most families will not seek or persist in care. The process may require multiple primary care visits.

Reinforce strengths of the youth and family as a method of engagement and identify any barriers to addressing the problem (eg, stigma, family conflict, resistance to academic testing or special education). Use "common factors" techniques to build trust and optimism, reach agreement on incremental next steps, develop a plan of care, and collaboratively determine the role of the primary care physician. Regardless of other roles, the primary care physician can encourage a positive view of treatment on the part of the youth and family.

### Encourage Healthy Habits

Encourage exercise, outdoor play, balanced and consistent diet, sleep (critically important to mental health), avoidance of exposure to frightening or violent media, limitation of screen time to less than 1 to 2 hours per day, special time with parents, acknowledgment of child's strengths, and special efforts to support the child and help him or her to feel competent, special, positive, and appreciated.

### Reduce Stress

Consider the child's social environment (eg, family social history, parental depression screening, results of any family assessment tools administered, reports from child care or school). Questions to raise might include the following:

*Is the parent punitive or critical?* If parents' psychosocial problems are affecting their relationship with the child, explore their readiness to address these problems as part of helping their child. Encourage praise for their child's efforts. Urge parents to avoid comparisons with siblings or peers and to keep up the child's self-esteem. Urge parents to nurture the child's nonacademic gifts, such as art or music, and encourage participation in extracurricular activities that provide social experiences uncomplicated by academic performance and competition (eg, scouts, faith-based youth group, boys' or girls' club).

## BOX 172-5 Guidelines for Homework Battles

- Establish a routine (not waiting until evening to get started).
- Identify another student your child can call to clarify homework assignments.
- Limit distractions (eg, TV, computer, phone).
- Assist child in dividing assignments into small, manageable segments (especially important for long-range assignments and large projects).
- Assist child in getting started (eg, read directions together, watch child complete first items).
- Monitor without taking over.
- Praise good effort and completion of tasks.
- Do not insist on perfection.
- Offer incentives ("When you've finished, we can . . .").
- Help child study for tests.
- Do not force child to spend excessive time on homework; write a note to the teacher if the child put forth good effort but was not able to complete it.
- If child fails to turn in completed work, develop a system with the teacher to collect it on arrival.
- If unable to provide homework supervision and assistance, or if homework battles are adversely affecting the parent-child relationship, ask the teacher for help finding a tutor.

*Are there battles over homework?* Advise parents that the child is not lazy. Provide guidance about helping with homework (and requesting modified assignments, as appropriate). See Box 172-5 on Guidelines for Homework Battles.

*Is the child exposed to criticism or teasing at school? Is the child's teacher supportive and patient?* Provide strategies for communication between school personnel and home; coach them to praise progress and effort, not just outcomes, and to address teasing or bullying.

*Are school authorities proceeding with assessment in accordance with the child's rights?* Inform parents about the child's rights under the Individuals with Disabilities Education Act (IDEA) and Section 504 of the Rehabilitation Act. It is important to obtain information about how these 2 acts are specifically implemented in your state and school districts. If a child has a learning disability, he or she qualifies for specialized educational services, and IDEA requires that the school develop an Individual Education Plan (IEP). The IEP documents the child's current level of functioning, establishes goals, and delineates the services needed to meet those goals in the least restrictive environment possible. The parent is entitled to meet with school personnel to review and approve the IEP. If the child does not qualify for specialized educational services but has minor challenges that can be helped by minor classroom modifications (eg, preferential seating, homework modifications), the school may develop a 504 plan for the child. If the parent is dissatisfied with

the school's response to the child's needs, there is an appeal process within the school system.

If the school is not adequately addressing the child's needs, the physician may offer referral to a community mental health professional such as a psychologist or developmental-behavioral pediatrician, or an educational tutor. Results of this assessment may provide support for the parent's advocacy efforts in the school system or may guide the family in developing tutorial assistance for the child.

Whatever interventions are planned, it is important to acknowledge and reinforce protective factors (eg, good relationships with at least 1 parent or important adult, pro-social peers, concerned or caring family, help-seeking, and connection to positive organization[s]).

### Offer Initial Interventions

The strategies described below are applicable to the care of children with mild or emerging learning difficulties, as well as diagnosed learning disorders. They can also be used as initial primary care management of children with learning difficulties while readying children for further assessment or educational services or awaiting access to evaluation and treatment.

*Address comorbid conditions.*

*If there are battles over homework, offer guidelines to parents.* Box 172-5 provides guidelines for parents to address homework battles.

### Provide Resources

Families may find the National Center for Learning Disabilities ([www.ncl.org](http://www.ncl.org)) a helpful source for information and support. Parents with questions about special education law may wish to consult a dedicated resource like Wrightslaw ([www.wrightslaw.com](http://www.wrightslaw.com)). Helpful brochures, publications, and Web sites are included in Tools for Practice: Engaging Patient and Family.

### Monitor the Child's Progress Toward Educational Goals

School reports can be helpful in monitoring progress. Screening instruments that gather information from multiple reporters (youth, parent, teacher), such as the SDQ, can be helpful in monitoring progress with symptoms and functioning.

### Involve Specialist(s)

*Involve education or mental health specialist(s) if child does not respond to initial interventions or if indicated by the following clinical circumstances:*

- The child or parent is very distressed by the symptom(s).
- There are co-occurring behavior problems not responsive to primary care management.
- School evaluation is incomplete or untimely.
- Parent's relationship with school is adversarial.
- Child and family have conflicts not responsive to primary care management.
- Parent is very negative toward child or unresponsive to primary care guidance.

*Consider seeing a geneticist for a diagnostic genetic workup if there are persistent concerns that interventions are not producing results.*

*Reach agreement on respective roles in the child's care.* The primary care physician may be responsible for advising the family about the child's rights under IDEA; reducing stresses on the child while awaiting further assessment and treatment; engaging and encouraging the child's positive view of his or her evaluation and specialized instruction; monitoring academic progress; observing for and addressing any comorbidities; and coordinating care provided by parents, school, medical home, and specialists. Resources available to help physicians in this role are provided in Tools for Practice. The primary care physician may also review with the family whether the child's school interventions are evidence-based ones, or refer to a developmental-behavioral pediatrician who is more knowledgeable in this area.

## Chapter 173 LIMP

Ginger Janow, MD; Norman T. Ilowite, MD

Limp is a common presenting complaint in both pediatric primary care offices and emergency departments. While the most common cause of limp is trauma, there are many other etiologies, ranging in severity from benign to life-threatening. Limp is defined as an abnormal gait pattern. Distinguishing a limp in a young child can be particularly challenging as the mature gait cycle does not fully develop until after 7 years of age.

## DIFFERENTIAL DIAGNOSIS

### General

The differential diagnosis of a limp is broad, and is best considered as 7 categories: trauma, vascular, infectious, malignancy or tumor, skeletal anomalies, inflammatory diseases, and neuromuscular disorders.

### Trauma

The most common cause of limp is trauma. If the history and physical examination suggest a fracture, ligament damage, or tendon damage, the patient should be referred to an orthopedist. Otherwise, rest, ice, compression, elevation, and analgesics are the mainstays of therapy. Radiographic evaluation should be guided by the history and physical examination.

### Vascular

**Legg-Calvé-Perthes disease** is characterized by avascular necrosis of the femoral head. Most often seen in the 5- to 10-year-old age group, it is more common in boys than girls. Patients generally present with groin or referred knee pain and an antalgic limp, with increased pain on activity. On examination, they generally have pain and limitation upon internal hip rotation. Early in the course, plain radiographs may be normal or may show increased density of the femoral head on the affected side, but later will show subchondral lucency, and ultimately, collapse and destruction of the femoral epiphysis (Figure 173-1). Once the diagnosis is suspected, pediatric orthopedics should be consulted for further workup and management.

**Osteochondritis dissecans** is the result of ischemia of the subchondral bone and can occur in multiple joints, although the knee is the most common. It generally occurs in adolescents, and most often presents with knee pain, swelling, and the sensation of the knee giving way. On physical examination, there is often joint swelling and pain on motion. Plain radiographs

**Figure 173-1** AP pelvis in an 8-year-old boy with right hip pain and limp. Right femoral head epiphysis shows loss of height and mixed sclerotic and lytic appearance (arrows) of Legg-Calvé-Perthes disease. (From Barkin RM, Barkin SZ, Barkin AZ. *The limping child*. *J Emerg Med*. 2000;18[3]:331–339. Copyright © 2000, Elsevier, with permission.)

reveal a radiolucent zone separating the osteochondral fragment from the rest of the bone.

### Infectious

**Septic arthritis**, or infection within the joint space, is among the most emergent causes of a limp, requiring rapid identification and treatment to avoid long-term damage and disability. The 2 peaks in incidence are in the toddler years and in adolescence. In most cases, the onset of pain is rapid and is accompanied by a fever and refusal to bear weight. On physical examination, the joint is generally swollen, warm, tender, and extremely painful with range of motion. If a septic joint is suspected, laboratory evaluation should include evaluation of synovial fluid (with Gram stain, culture, and cell count), blood culture, complete blood count (CBC), sedimentation rate (ESR) and C-reactive protein (CRP). Plain radiographs may reveal a joint effusion. An ESR of less than 20 mm/hr or a normal CRP lowers the likelihood of a serious infectious cause but does not exclude the diagnosis of skeletal infection. Etiologic agents are isolated in the blood or synovial fluid in 34% to 82% of cases. Synovial fluid generally reveals an elevated white blood cell count with increased segmented neutrophils (Table 173-1).

In the toddler age group, the most common organisms are *Staphylococcus aureus*, *Kingella kingae*, and in young infants. *Haemophilus influenzae* type b (Hib) previously accounted for 70% of cases of septic arthritis in children from 2 months to 2 years of age, but this pathogen has been virtually eradicated following universal Hib vaccine implementation. Group B *streptococcus* is the most common cause of invasive bacterial infection in infants less than 2 months of age, and both bone and joint infection can occur. In the adolescent age group, *S aureus* is still the most common pathogen, but gonococcal arthritis should be considered in the sexually active teen. If septic arthritis is suspected, orthopedics should be consulted for joint aspiration and drainage should be promptly performed in cases of hip or shoulder infection. Gram stain and culture, when positive, should guide antibiotic management.

**Osteomyelitis** is most common in the toddler age group but can be seen in all age groups, and is usually caused by the same organisms responsible for septic arthritis. The pathogenesis of infection is generally hematogenous seeding, but osteomyelitis may follow penetrating trauma or deep contiguous infection as may occur with decubitus ulcers. Involvement of long bones is most common; femur or tibia are the 2 most common sites reported. Patients often present with fever, pain in the affected extremity and limp, and may report preceding trauma. Physical examination findings are dependent upon the location of the infection, but point tenderness over the bony metaphysis is highly suggestive of osteomyelitis in the child with limp. Plain radiographs are often negative upon presentation, but generally show abnormalities 10 to 21 days after onset. Magnetic resonance imaging (MRI) scan may be diagnostic and should be used to guide surgical drainage if subperiosteal abscess is suspected. Laboratory evaluation is similar to that for septic arthritis. An orthopedist must be involved in the management, and input from an infectious diseases specialist is often helpful in the choice of antibiotic treatment. *S aureus* is far and away the most common pathogen associated with hematogenous osteomyelitis in children. *Pseudomonas aeruginosa* is a notable pathogen following nail puncture wounds involving the foot. Of note, children with sickle cell disease are especially at risk for osteomyelitis, and *Salmonella* is more often the responsible agent than *Staphylococcus*.

**Diskitis**, a relatively rare infection of the disk space, is most common in toddlers. Patients usually have a limp, or refuse to walk, sit, or perform any motion that requires range of motion of the affected region of the spine. Physical examination reveals pain over the involved disc space and decreased range of motion of the spine. The child generally does not seem ill or febrile, but may have increased inflammatory markers. The causative organism is usually *Staphylococcus aureus*, and treatment includes antibiotics and rest.

**Table 173-1** Characteristics of Synovial Fluid

GROUP AND CONDITION	COLOR AND CLARITY	VISCOSITY	WBC COUNT	PMN (%)
<b>NONINFLAMMATORY</b>				
Normal	Yellow and clear	Very high	<200	<25
Traumatic arthritis	Xanthochromic and turbid	High	<2,000	<25
Osteoarthritis	Yellow and clear	High	1,000	<25
<b>INFLAMMATORY</b>				
Systemic lupus erythematosus	Yellow and clear	Normal	5,000	10
Rheumatic fever	Yellow and cloudy	↓	5,000	10–50
Chronic arthritis	Yellow and cloudy	↓	15,000–20,000	75
Reactive arthritis	Yellow and opaque	↓	20,000	80
<b>PYOGENIC</b>				
Tuberculosis arthritis	Yellow-white and cloudy	↓	25,000	50–60
Septic arthritis	Serosanguineous and turbid	↓	50,000–300,000	>75

### Malignancy or Tumor

**Leukemia** presents with musculoskeletal pain in 15% to 30% of cases, and is most common in the 2- to 5-year-old age group. The limp is usually accompanied by systemic symptoms, including fever, pallor, and fatigue. History will often reveal pain that wakes the patient from sleep and is generally out of proportion to findings on clinical examination. On physical examination, the child may have frank arthritis, bone tenderness, or bone pain. Laboratory evaluation will often show an abnormally high or low WBC count with anemia and thrombocytopenia. Thrombocytopenia and night waking can help differentiate malignancy from systemic juvenile idiopathic arthritis, which can also manifest as joint pain with systemic symptoms. Plain radiographs may reveal leukemic lines, which appear as metaphyseal sclerotic bands, and osteopenia.

**Osteosarcoma** is a malignant tumor seen primarily in adolescents. Patients often report night waking with pain and have tenderness at the affected site. Plain films generally show an abnormality in the bone, most often in the metaphyses of long bones. Once osteosarcoma is suspected, the patient should be immediately referred to a pediatric oncologist.

**Osteoid osteoma** is a benign tumor seen throughout childhood and adolescence. Patients typically have localized pain that is worse in the evenings and responds dramatically to nonsteroidal anti-inflammatory drugs. If left untreated, the tumor can cause asymmetric limb growth. Plain radiographs typically reveal cortical thickening and sclerosis with a less than 1 cm radiolucent nidus (Figure 173-2). However, the nidus is not visible on plain radiographs in 15% of cases. Therefore, if the index of suspicion is high, computed tomography (CT), MRI, or bone scan should be pursued to establish the diagnosis.

**Figure 173-2** Osteoid osteoma. Views of the midshaft of the femur demonstrate a dense sclerotic lesion with cortical thickening containing a small oval lucent nidus (arrow). (From Eisenberg RL. *An Atlas of Differential Diagnosis*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003. Copyright © 2003 Lippincott Williams & Wilkins.)

### Skeletal Anomalies

**Congenital hip dysplasia** is most commonly diagnosed in infancy but can manifest as a delay in walking or as an abnormal gait in the toddler age group. On physical examination, there is typically decreased abduction and extension of the affected hip with 1-sided toe walking to compensate for an apparent leg-length discrepancy. Beyond infancy, the anomaly is visible on standing radiograph (Figure 173-3). In the newborn period an ultrasound is generally diagnostic. Treatment after the newborn period generally requires surgical intervention, and referral to a pediatric orthopedist is necessary.

**Discoid meniscus** is a condition most commonly seen in school-aged children, in which the lateral meniscus is discoid rather than crescent-shaped. Patients often report pain with activity. On physical examination, the physician may notice swelling of the knee or the inability to fully extend the knee, as well as tenderness along the lateral joint line. Plain radiographs are normal and MRI is required for diagnosis.

**Tarsal coalition**, or abnormal ossification between the talus or navicular and calcaneus, generally occurs in adolescents and is often associated with foot pain. The physical examination reveals a stiff, flat foot in eversion with contracture of the peroneal muscles. Tarsal coalition can often be diagnosed on oblique radiographs of the ankle joint; however, if the plain radiograph is negative but there is a high index of suspicion, CT may be diagnostic. Management initially involves rest but may involve surgery in severe cases.

**Slipped capital femoral epiphysis (SCFE)** most commonly occurs in the 10 to 16 year age group and is more common in black than Hispanic children, and more common in Hispanic than white children.

**Figure 173-3** AP pelvis in a 14-month-old girl with an abnormal gait and difficulty walking. The left proximal femur is displaced superolaterally. The white arrow shows a small capital femoral epiphysis. The black arrow shows a steep acetabular roof. The patient had previously unrecognized developmental dysplasia of the left hip. Contrast in the bladder is from a voiding cystourethrogram. (From Barkin RM, Barkin SZ, Barkin AZ. *The limping child*. J Emerg Med. 2000;18[3]:331-339. Copyright © 2000, Elsevier, with permission.)

Obese adolescent males have a higher rate of SCFE as do children with hypothyroidism, low growth hormone level, pituitary tumors, craniopharyngioma, Down syndrome, renal osteodystrophy, and adiposogenital syndrome. It occurs when the femoral epiphysis slides posteriorly, resulting in limited internal rotation of the hip. Symptom onset can be acute or insidious with weeks to months of intermittent vague symptoms before the patient seeks medical attention. Plain radiographs in the frog-leg position are generally diagnostic (Figure 173-4). Patients suspected of having SCFE should be referred to a pediatric orthopedist for surgical management.

### Inflammatory Diseases

**Juvenile idiopathic arthritis (JIA)** is the general term used to describe arthritis lasting for greater than 6 weeks in a child 16 years or younger with no known cause. The specific subtype of JIA is determined by the number of joints and specific joints involved, associated systemic symptoms, and HLA-B27 positivity. The age of onset varies by subtype. Symptoms at onset include joint pain and swelling, limp, morning preponderance of pain, and morning stiffness. With systemic JIA, patients may also report fever and rash. Physical examination reveals arthritis in 1 or more joints, most often the knee. Arthritis manifests as swelling, limitation of motion, warmth, with pain on motion and/or tenderness. If present, leg-length discrepancy and muscle atrophy of the affected extremity suggest a chronic process. Laboratory evaluation should be performed to rule out other causes of arthritis and to assess inflammatory markers. Lyme serology (only in those from or who visited endemic areas), antistreptolysin O titer, and parvovirus should be sent in the appropriate clinical setting as well as a CBC, ESR, and CRP. Once the diagnosis of JIA is made, additional laboratory tests including rheumatoid factor, anticyclic citrullinated peptide antibody, antinuclear antibody,

and HLA-B27 typing can help clarify subtype. Plain radiographs may reveal a joint effusion or joint-space narrowing and erosions, but are often normal. If JIA is suspected, the patient should be referred to a pediatric rheumatologist for further workup and treatment.

**Systemic lupus erythematosus** is a chronic autoimmune disease affecting multiple organs associated with antinuclear antibodies. It is more common in black, Asian, and Hispanic females. One of the many symptoms associated with lupus is a nonerosive arthritis which can present with a limp. If there are other symptoms of lupus present and the index of suspicion is high, laboratory workup should include an antinuclear antibody, CBC, and a urinalysis, as well as the work up mentioned above to rule out infectious causes of arthritis. If lupus is suspected, the patient should be referred to a pediatric rheumatologist for further workup and treatment.

**Transient synovitis** most often presents as hip arthritis in children between the ages of 3 and 8 years. It may be preceded by a viral infection. It is generally less symptomatic than septic arthritis, without associated fever, and inflammatory markers may be normal or only mildly elevated. Transient synovitis generally lasts for 7 to 10 days. The patient often presents with a limp but is not ill-appearing. Physical examination commonly reveals pain on motion of the hip with mild limitation. Treatment generally includes rest and nonsteroidal anti-inflammatory medication, and symptoms generally resolve spontaneously.

**Juvenile dermatomyositis (JDM)** is a chronic autoimmune inflammatory myopathy and vasculopathy typically presenting with a heliotrope rash, Gottron papules (violet-colored inflammatory lesions over the knuckles) and proximal muscle weakness. Arthritis can also occur. Laboratory evaluation reveals elevated muscle enzymes, and noncontrast fat-suppressed MRI shows proximal muscle edema. Patients suspected of having JDM should be referred to a pediatric rheumatologist.

**Figure 173-4** AP pelvis in a 13-year-old boy complaining of left hip pain and limp. A Klein line is drawn along the superolateral cortex of the femoral neck. The arrow shows posteromedial slippage of the left femoral epiphysis and widening of the physis, consistent with SCFE. (From Barkin RM, Barkin SZ, Barkin AZ. *The limping child*. J Emerg Med. 2000;18[3]:331–339. Copyright © 2000, Elsevier, with permission.)

### Neuromuscular Disorders

**Cerebral Palsy (CP)**, a nonprogressive motor disorder that develops in the first 3 years of life, is the most common neurologic cause of limp in a child. The disease itself is highly variable. Physical examination may reveal spasticity of the knee or ankle joint with hyperreflexia and clonus. Patients with CP often benefit from evaluation by a pediatric neurologist and a pediatric physiatrist.

**Muscular dystrophy (MD)**, most often the X-linked Duchenne type, typically affects children between the ages of 2 and 5 years and often first manifests as delayed ambulation. The patient may demonstrate toe walking and a positive Gower sign (inability to rise from the floor without leaning on his legs with his hands), as well as proximal muscle weakness. On laboratory examination, the serum creatine phosphokinase is elevated. Patients suspected of having MD should be referred to a pediatric neurologist.

## EVALUATION

### History

The history is crucial in narrowing the differential diagnosis of a limp. The physician should first rule out

any known trauma. If the mechanism of injury described by the parent or child does not correlate with the physical findings, nonaccidental trauma should be considered. Careful details regarding the duration of symptoms, exact location (asking the child to point with 1 finger may be helpful), acuity of onset, time of day of symptoms, quality of pain, and severity are often important for making a diagnosis.

**Duration:** An acute-onset limp is more likely to result from a mechanical problem, specific hip disorder, or a transient infectious process. Limp that lasts for longer than 6 weeks is more consistent with chronic causes such as JIA or malignancy.

**Location:** While asking for a specific location of the pain is important, consider that some pain in the lower extremity is referred. Hip pathology is generally reported as groin pain, but can also be referred to the knee. Pain over the greater trochanter is less likely from pathology of the hip itself and may represent inflammation of the trochanteric bursa (rare in children) or enthesitis. Pain specific to the shaft of the bone outside the setting of trauma is more concerning for malignancy or focal lesions and less consistent with joint pathology.

**Timing of symptoms:** Limp that occurs in the morning and resolves as the day goes on is characteristic of inflammatory joint pain, as seen in arthritis. Pain or limp that worsens with activity is more likely to be from biomechanical factors secondary to trauma or overuse. Unilateral pain that wakes the child at night is worrisome for malignancy or osteoid osteoma.

**Severity:** Pain that is severe or limits activity or function is concerning.

**Systemic symptoms:** Fever or weight loss is more suggestive of an infectious, oncologic, or inflammatory cause. Rash may give helpful clues to the diagnosis, as in the case of Lyme arthritis, parvovirus-associated

arthritis, Henoch-Schönlein purpura, or systemic-onset JIA.

### Physical Examination

The extent and focus of the physical examination should be tailored to the individual based on the history obtained. If any indication of systemic illness exists, then a complete examination should be conducted. In the absence of systemic signs, most of the examination can be directed toward the back and lower extremities. Complaints of thigh or knee pain may be referred from a hip process and require thorough evaluation of the hip joint. Particularly with younger children, a great deal of useful information may be gained by opportunistic observation of the child before entering the examination room or when engaged in other activities.

### Gait Examination

A normal, mature, synchronous gait consists of a stance phase (weight-bearing phase), which begins with the heel-strike and plantar-flexion and ends with toe-off. This leads into the swing phase which starts with toe-off and finishes with heel-strike. This phase requires forward rotation, pelvic tilt, and lumbar spine stability to ensure a coordinated gait. Determining the phase of gait affected can help elucidate the cause (Table 173-2).

### Joints and Musculoskeletal Examination

General inspection of the lower extremities for evidence of skin breakdown, ecchymosis, erythema, or swelling may help localize the problem, using the non-affected limb for comparison. A side-to-side disparity in leg length or muscle bulk suggests chronicity. Leg length can be measured from the anterior superior iliac spine to the distal end of the ipsilateral medial malleolus. Palpation of the extremity along all surfaces can also help localize focal pathology.

**Table 173-2** Gait Abnormalities and Associated Pathology

TYPE OF GAIT ABNORMALITY	CAUSE	DESCRIPTION	ASSOCIATED PATHOLOGY
Antalgic	Pain on weight bearing	Shortened stance on affected leg with shortened swing phase on contralateral side	Soft-tissue or skeletal trauma, chondromalacia patellae, arthritis, osteomyelitis, inguinal lymphadenitis, abdominal infection, Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, bone neoplasia, rickets, tarsal coalitions
Vaulting	Joint pain or muscle weakness	Straight-legged walking (locking of knee causes the child to “vault” over leg)	Arthritis, skeletal dysplasias, congenital short femur, neurologic and neuromuscular disease, soft-tissue infection (dependent on affected joint/site)
Steppage	Peroneal nerve injury or weakness of the tibialis anterior muscle	Foot drop	Congenital talipes equinovarus, chronic pain syndromes
Trendelenburg	Hip abductor weakness or hip joint instability	Hip girdle drops on affected side, trunk moves over affected side to maintain balance	Hip arthritis, myositis, osteomyelitis, soft-tissue infection, abdominal infection (including psoas abscess, appendicitis, peritonitis), Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, developmental dysplasia of the hip, neurologic disease, dermatomyositis and neuromuscular disease

Each joint of the lower extremity should be evaluated independently for evidence of trauma or inflammation. Range of motion, size and contour should be symmetric, emphasizing the importance of side-to-side comparison. If joint involvement is suspected, the joints of the upper extremities and spine should be fully evaluated as well.

### **Sacroiliac (SI) joint**

The sacroiliac joint is where the sacrum attaches to the ilium. On physical examination, the joint can be palpated directly under the dimples of Venus. The Gaenslen maneuver, in which the patient hangs 1 leg off the table and pulls the opposite knee towards the chest, is a test for inflammation of the sacroiliac joint (Figure 173-5). The test is considered positive if the patient has pain in the buttock opposite the knee that is being held. The SI joint is often involved in 1 of the subtypes of JIA, enthesitis-related JIA; alternatively, insidious infection of the SI joint can occur.

### **Hip joint**

Children with hip pathology tend to hold the joint in a flexed, abducted, and externally rotated position, taking pressure off of the joint. The hip joint can be isolated on physical examination using a maneuver called the logroll. The examiner places a hand on the mid-thigh and mid-shin of the patient and gently rolls the hip internally and externally, taking care not to simultaneously manipulate the knee joint.

### **Knee joint**

The knee should be compared to the contralateral knee to assess for swelling, which often manifests as a loss of bony landmarks. The knee should be assessed for warmth and tenderness, as well as pain on motion or limitation of motion with either flexion or extension. Patellofemoral syndrome (formerly known as chondromalacia patella) can be assessed with the patellar inhibition test, whereby the examiner applies pressure to the

patellar tendon proximal to the patella, and asks the patient to tense the quadriceps muscles. If this reproduces the patient's pain, it is considered a positive test. Anterior cruciate ligamentous (ACL) injury can be assessed using the anterior drawer test: with the patient lying flat and the knee bent at 90 degrees, the examiner pulls the calf forward. If the tibial excursion is greater than normal, the test is considered positive and is suggestive of loss of ACL integrity. A Lachman maneuver is an appropriate substitute to evaluate the integrity of the ACL: the knee is placed at 30 degrees of flexion, and while the femur is stabilized with 1 of the examiner's hands the tibia is pulled anteriorly with the other hand (Figure 173-6). If there is no clear end point of anterior movement, or absence of a "clunk," the test is considered positive. The posterior drawer test is used to assess for injury to the posterior cruciate ligament (PCL), and is performed similarly to the anterior drawer test, but the shin is pushed posteriorly; excessive posterior movement is suggestive of PCL injury. Injury to the lateral collateral ligament (LCL) and medial collateral ligament (MCL) can be assessed by placing the patient flat on the back with the knee held at 30 degrees of flexion; the shin is shifted from side to side to test the integrity of the LCL (varus stress) and MCL (valgus stress). To assess for meniscal injuries, first palpate over the joint line for tenderness. The McMurray test examines the integrity of the medial and lateral menisci. To test the medial meniscus, the patient lies in the supine position with the knee in full flexion; with 1 hand, the examiner stabilizes the joint, applying pressure to the lateral aspect of the joint providing valgus stress, while with the opposite hand the examiner holds the heel of the patient and laterally rotates the tibia while extending the knee. To assess lateral meniscal

**Figure 173-5** Pain with this maneuver is indicative of pathology within the sacroiliac joint.

**Figure 173-6** With one hand stabilizing the femur, the proximal tibia is moved forward with the other hand. The absence of a distinct endpoint of forward tibial movement is suggestive of ACL injury.

integrity, the medial meniscus is stabilized by 1 hand while the tibia is rotated medially and the knee is extended by the other hand. If the patient has pain or the examiner feels a snap or click, the test is positive.

### Ankle

The ankle is comprised of 2 joints, the tibiotalar joint and the subtalar joint. The tibiotalar joint is responsible for dorsiflexion and plantar flexion, and the subtalar joint is responsible for inversion and eversion. Pain over the Achilles tendon or at the sites of attachment of the plantar fascia may be suggestive of a tendonitis, or in the setting of chronic pain, may be associated with enthesitis related to JIA.

### General Examination

On initial examination, the most important determination is whether or not the patient is ill-appearing, as this may be associated with more urgent problems such as a septic joint or a systemic disease. The patient should be assessed for any rashes or lesions suggestive of specific disorders. A thorough neurologic assessment should be performed, including an evaluation of muscle strength and function, sensation, and reflexes.

### Laboratory Testing

In cases of known trauma, blood testing is often not necessary. A CBC and measure of acute phase reactants are useful if inflammatory or infectious causes are suspected (see Differential Diagnosis for specific laboratory abnormalities by disease). If a septic joint is likely, joint aspiration should be performed and blood cultures should be obtained prior to initiation of antibiotics. Antinuclear antibody (ANA) testing in the absence of objective evidence of arthritis is not necessary unless there are additional clinical findings suggestive of autoimmune disease (vasculitic/malar rash, palatal ulcers, hair loss, serositis, renal or CNS disease). In the setting of chronic arthritis, the ANA is useful to delineate risk of developing uveitis, but it is not diagnostic. Approximately 20% of healthy children have a positive ANA without any underlying disease. If arthritis is seen on physical examination and the history is suggestive of the associated diseases, Lyme titers, gonococcal cultures, parvovirus IgG and IgM, anti-DNAse B and antistreptolysin O titers may be warranted.

### Imaging

#### Radiographs

Plain-film radiographs remain an important tool in the evaluation of limp, particularly in diagnosing fractures, hip disease, spinal abnormalities, and foot disease (eg, tarsal coalition). Obtaining at least 2 views of the affected area is essential; with suspected hip disease, the 2 views should be the anteroposterior (AP) and frog-leg lateral (Lauenstein) views of the pelvis. Diagnosis-specific radiographic findings are reviewed in the Differential Diagnosis section.

#### Ultrasound

Ultrasound can be used to assess musculoskeletal pathology. Joint effusions, synovial thickening, and increased blood flow seen by power Doppler are suggestive of underlying inflammation. While the cause of inflammation cannot be determined by this method, it

may be a useful adjuvant to the history and physical examination.

### Bone Scintigraphy

Bone scintigraphy measures the uptake of technetium-99m, which is increased at sites of high bone turnover. It is therefore most useful in the diagnosis of osteomyelitis, diskitis, stress fractures, osteoid osteomas, Legg-Calvé-Perthes disease, and neoplasm, especially if the location of the pathology is difficult to identify. However, MRI is often preferred to bone scintigraphy to spare children radiation exposure and to provide more specific information.

### Computed Tomography

Computed tomography is most useful for evaluating bony pathology, including tarsal coalition, spondylolisthesis, spondylolysis, or osteoid osteoma. However, it exposes the patient to a high dose of radiation and its use should therefore be limited to situations where other imaging modalities are inadequate or unavailable.

### Magnetic Resonance Imaging

Magnetic resonance imaging offers information about bone formation and inflammation as well as soft tissues without exposing the child to radiation, and is therefore the imaging modality of choice for clarifying difficult diagnoses. In cases of arthritis, osteomyelitis, diskitis, stress fractures, osteoid osteomas, Legg-Calvé-Perthes disease, and neoplasm, MRI is often crucial to diagnosis.

## WHEN TO REFER

Limp is a common presenting complaint in pediatric emergency departments and primary care offices. History and physical examination are crucial to diagnosing the cause of a limp, and imaging is an important adjuvant to the physical examination. There are very few emergent causes of limp, but they do occur, and suspicion of any of the following causes does warrant referral:

- Septic joint
- Malignancy
- Surgical cause (eg, appendicitis, psoas abscess)
- Serious fracture

Once these emergent causes of limp have been excluded, if the workup is negative, an observation period of 1 to 2 weeks may be appropriate. Following the observation period, if the diagnosis is still unclear, referral to an orthopedist, rheumatologist, or neurologist may be necessary depending on the clinical scenario.

## Chapter 174

# LOSS OF APPETITE

Nancy McGreal, MD; Martin H. Ulshen, MD

Loss of appetite (anorexia) is a common symptom in children. Acute illness in childhood is often associated with transient loss of appetite. Prolonged loss of appetite associated with poor weight gain or loss of weight usually signifies a serious chronic illness, either organic or psychogenic.

## PATHOPHYSIOLOGIC FEATURES

The mechanisms that regulate hunger and satiety are complex and redundant, remaining incompletely understood. Appetite is regulated by multiple nuclei and signaling pathways in the hypothalamus, now known to be much more complex than the previously described *satiety center* in the ventromedial hypothalamus and the *feeding center* in the lateral hypothalamus. The hypothalamus detects peripheral signals, including gut hormones and blood-borne nutrients. Vagal nerve afferents from the gastrointestinal (GI) tract and hepatoportal region terminate in the brainstem, and information is conveyed to the hypothalamus. Both appetite-stimulating and appetite-suppressing neuropeptides are secreted in the hypothalamus. Central control of appetite is influenced by anticipation of a pleasurable meal, visual and taste sensations, ambient temperature, and changes in blood levels of glucose or other nutrients, as well as by limbic signals from higher central nervous system (CNS) regions. Initiators of satiety include vagal input from gastric distention, cholecystokinin from the intestine and CNS, and other humoral factors, including insulin, glucagon-like peptide-1, pancreatic polypeptides, and endorphins. Each individual may have a set point for body fat content. Deviations may cause alterations in diet intake, a process apparently mediated by the interaction of the hormones leptin, produced in adipose cells, and ghrelin, produced by endocrine cells in the stomach and GI tract, with receptors in the hypothalamus. Leptin suppresses and ghrelin stimulates appetite. Changes in the levels of these hormones influence the release of CNS neuropeptides, including neuropeptide Y, melanocyte-stimulating hormone, and the orexins.

Cytokines are key mediators of the appetite suppression that occurs with acute and chronic illnesses. Interleukin-1 $\beta$ , interleukin-6, and tumor necrosis factor- $\alpha$ , for example, have been shown to induce anorexia by acting directly on the hypothalamus. Effects on the peripheral nervous system and on hormone levels occur as well.

## DIFFERENTIAL DIAGNOSIS

When considering anorexia, the physician must first separate complaints based on unrealistic parental dietary expectations from justified parental concern over a child's diminished nutritional intake. In the

former situation, the child is typically growing well and appropriately thriving. Although significant GI disease commonly leads to poor appetite, anorexia may be the result of disease that is distant from the bowel. In the newborn period, poor oral intake by an infant who is developmentally capable of feeding may be the first indication of a major disorder, such as sepsis, meningitis, urinary tract infection, congenital viral infection, a GI anomaly, CNS disease, renal failure, or an inborn error of metabolism.

During infancy, a wide spectrum of causes can account for inadequate caloric intake. An acute infectious disease is a common cause of transient anorexia in infants. If no obvious explanation exists for poor feeding, then the pediatrician should always consider the possibility of an oral disease (eg, thrush), gastroesophageal reflux disease, eosinophilic esophagitis, renal tubular acidosis, dietary protein intolerance, or a neurologic disorder. Occasionally, an infant will lack interest in feeding from the first days of life but in every other respect will appear normal; such an infant may well need enteral feeding supplementation. Emotional deprivation is a common cause of failure to thrive; a thorough social history is essential to the evaluation. Early observation of parent-infant interaction in the hospital, including feeding techniques, may be helpful. An infant who has not received oral feedings for a prolonged period because of medical problems (eg, esophageal disease, short bowel syndrome) may not be interested when feedings are introduced by mouth. The mother and infant may require training (typically provided by an occupational therapist, physical therapist, or speech pathologist) and gradual advancement of an oral diet.

Box 174-1 presents a list of causes of loss of appetite that are applicable to both infants and children. Generally, the best approach to anorexia is to treat the underlying condition.

## EVALUATION

In formula-fed infants, a state of chronically inadequate caloric intake can be identified objectively by computing the total calories ingested, most of which come from formula, and comparing this total with the estimated caloric requirements for weight. Such computation is more difficult with breastfed infants, although intake may be established by weighing the infant before and after feedings. If the nursing infant has a reduced intake, the physician must establish whether maternal milk production is inadequate or the infant is too weak or disinterested to nurse.

In older children and adolescents, an adequate evaluation of nutritional intake requires careful calorie counts. If the possibility of malabsorption is a concern, a calorie count and 72-hour stool collection for fat analysis may be ordered. Separating children who have poor appetites from children who do not eat for fear of worsening their symptoms is important from the outset. Children with abdominal pain from chronic inflammatory bowel disease or chronic constipation may not eat because doing so increases their pain. Similarly, children with chronic diarrhea may find that eating less leads to less frequent stooling. These

**BOX 174-1 Causes of Decreased Appetite in Infants and Children****ORGANIC DISEASE**

- Infections (acute or chronic)
- Neurologic causes
  - Cerebral palsy
  - Congenital degenerative disease (eg, neurodegenerative disorders, spinomuscular atrophy, muscular dystrophy)
  - Hypothalamic lesion
  - Increased intracranial pressure, including a brain tumor
  - Static encephalopathy
- GI causes
  - Oral or esophageal lesions (eg, thrush, herpes simplex, dental caries, ankyloglossia)
  - Gastroesophageal reflux
  - Eosinophilic esophagitis
  - Dietary protein intolerance
  - Bowel obstruction (especially with gastric or intestinal distention)
  - Inflammatory bowel disease
  - Celiac disease
  - Constipation
  - Esophageal motility disorder (eg, cricopharyngeal dysfunction, achalasia, connective tissue disorder)
- Cardiac causes
  - Congestive heart failure or cyanotic heart disease
- Metabolic causes
  - Renal failure, renal tubular acidosis, or both

- Liver failure
- Inborn errors of metabolism
- Lead poisoning
- Nutritional causes
  - Marasmus
  - Iron deficiency
  - Zinc deficiency
- Drugs
  - Morphine
  - Digitalis
  - Antimetabolites
  - Methylphenidate
  - Amphetamines
  - Topiramate
- Prolonged restriction of oral feedings, beginning in the neonatal period
- Tumor
- Chronic febrile conditions (eg, rheumatoid arthritis, rheumatic fever)

**PSYCHOLOGICAL FACTORS**

- Anxiety, fear, depression, mania (limbic influence on the hypothalamus)
- Avoidance of symptoms associated with meals (abdominal pain, nausea, diarrhea, bloating, urgency, dumping syndrome)
- Anorexia nervosa
- Excessive weight loss and food aversion in athletes, simulating anorexia nervosa

children may actually not have anorexia, and treatment aimed at improving the other symptoms may result in rapid improvement in oral intake.

**TREATMENT**

Enlisting the help of a dietitian to plan diets can be useful for maximizing nutritional intake in older children. Nutritional supplements may be indicated, either high-calorie milkshakes or commercial high-calorie supplements. Several medications, including cyproheptadine and megestrol acetate, have been shown to stimulate appetite. Although cyproheptadine does not seem to affect appetite in all children treated, when successful, the response is dramatic. Megestrol acetate, a progesterone derivative, has been administered for cancer-related anorexia, primarily in adults. Its potential side effects on the endocrine system include adrenal insufficiency. Weight gained with megestrol acetate may be, to a large extent, from increased fat mass. Eicosapentanoic acid, an omega-3 fatty acid, has been evaluated in the treatment of adult and pediatric cancer-associated anorexia with equivocal results. In some disorders, such as congenital heart disease, initial nasogastric or

nasoduodenal infusion of nutrients may be necessary to promote growth. If prolonged supplementation proves necessary, a gastrostomy tube can be placed. Parenteral nutrition may be indicated in specific situations. However, expertise with this modality and close supervision are required, and caretakers need special training if the parenteral nutrition is to be provided at home. Refeeding after severe malnutrition requires careful consideration of potential cardiac and metabolic complications.

**WHEN TO REFER**

- Loss of appetite without an obvious explanation, especially in association with weight loss or failure to thrive
- Anorexia nervosa

**WHEN TO ADMIT**

- Weight loss or lack of weight gain that is unresponsive to outpatient management
- Requirement to initiate enteral or parenteral feeding because of inadequate oral intake

## Chapter 175 LYMPHADENOPATHY

Geoffrey A. Weinberg, MD; George B. Segel, MD;  
Caroline Breese Hall, MD†

Enlargement of 1 or more lymph nodes is a common finding in childhood. Lymphadenopathy may be defined as any lymph node enlargement; all lymph nodes that are palpable are technically considered enlarged. However, nodes in the cervical chain, occipital, and inguinal areas drain regions that are commonly infected in childhood and are often mildly enlarged (<1 cm in diameter) in children who are otherwise healthy.

The clinically relevant problems in assessing lymphadenopathy are whether any lymph node or lymph node aggregate or chain is abnormal and requires further assessment; if abnormal, whether the nodes are benign, primarily inflammatory, or malignant; and what the appropriate evaluation, diagnosis, and management should be.

### CHARACTERISTICS OF LYMPH NODE ENLARGEMENT

#### Components of the Lymphatic System

The lymphatic system includes not only lymph nodes but also the spleen, thymus, tonsils, Waldeyer ring, appendix, and Peyer patches in the intestine. Potentially palpable lymph node groups and their drainage areas are listed in Table 175-1. The location of the lymphatics of the head and neck and lymph node drainage are shown in Figure 175-1 and may serve as a guide to palpation of these superficial nodes.

#### Lymph Node Features

Abnormalities of the palpable lymph nodes are assessed by noting the node's size, location, mobility, tenderness, erythema (inflammatory reaction), and consistency and whether it is matted. Nodes smaller than 1 cm are often found in the cervical chain and in the femoral areas. They are often somewhat larger in the inguinal areas. Similarly, nodes smaller than 0.5 cm may be palpated in the occipital, postauricular (mastoid), and axillary chains. Small occipital and

postauricular nodes are common in infants but not older children, whereas cervical and inguinal nodes are common after age 2 years. The distribution by age is shown in Table 175-2. In the submental or submaxillary regions, intraoral or facial infections may enlarge the nodes to more than 1 cm. However, finding lymph nodes of any size in the supraclavicular or epitrochlear areas is unusual. Thus, lymph nodes of the same size observed in 2 different regions may have markedly different implications. For example, a 1-cm node in the cervical region of a 5-year-old child is very likely benign, whereas a 1-cm supraclavicular node requires a biopsy because it is unlikely to result from superficial inflammatory disease and may reflect intrathoracic or intraabdominal malignancy. Noninflammatory nodes greater than 2 to 2.5 cm require biopsy.

Fluctuance and signs of inflammation surrounding a group of enlarged lymph nodes are helpful in reaching a diagnosis, particularly if an infectious source is found distal to the node area. These findings strongly suggest an infectious, primarily bacterial cause (Table 175-3), usually requiring systemic antibiotic therapy. If no inflammation is found, the consistency is firm, and the nodes are not mobile, then an underlying malignancy may be present, such as a lymphoma, sarcoma, or neuroblastoma. Hard, fixed nodes are seen more often in adults who have metastatic carcinoma. The nodes of Hodgkin disease and lymphoma are more matted than hard, although nodes associated with neuroblastoma, rhabdomyosarcoma, and other childhood malignancies may mimic the findings in adults.

## DIFFERENTIAL DIAGNOSIS

The major differential diagnostic categories for enlarged lymph nodes include infectious (inflammatory), neoplastic, immunologic, storage, and other diseases. Table 175-3 provides a summary of the common and unusual conditions associated with lymphadenopathy.

### Infections

Infectious problems may be localized or systemic. If localized, the primary site of infection draining to the

involved lymph node area should be identified (see Table 175-1). Lymph nodes enlarge most often in reaction to a localized or generalized infection, but a node can itself become intrinsically infected, resulting in lymphadenitis.

The common pyogenic bacteria (*Staphylococcus aureus* and *Streptococcus pyogenes*), atypical mycobacteria, and *Bartonella henselae* (cat-scratch disease) are most likely to cause localized adenopathy. Generalized adenopathy or regional adenopathy associated

with adenopathy elsewhere is more likely caused by infections from viruses, spirochetes, or, sometimes, *Toxoplasma* spp. *Mycobacterium tuberculosis* may produce localized or multiple sites of adenitis. Fungal infections, such as histoplasmosis, occasionally cause generalized lymphadenopathy when disseminated, but most fungal infections, if associated with adenopathy at all, produce regional enlargement.

### Neoplastic Diseases

Primary neoplastic diseases are the other major consideration in both localized and generalized adenopathy. Included in this category are lymphomas, leukemia, histiocytosis, and metastases from solid tumors such as neuroblastoma, Wilms tumor, Ewing sarcoma, and rhabdomyosarcoma. If a mediastinal mass is identified, then the diagnostic considerations vary with the anatomic location within the mediastinum (Box 175-1).

### Immunologic and Inflammatory Diseases

Generalized lymphadenopathy also may be associated with chronic inflammatory conditions, such as juvenile idiopathic arthritis, other autoimmune diseases, and sarcoidosis; with reactions to certain drugs, such as phenytoin and isoniazid; or with serum sickness.

#### BOX 175-1 Anatomic Locations of Mediastinal Masses

##### ANTERIOR MEDIASTINUM

- Lymphoma
- Thymoma
- Malignant germ cell tumor
- Benign teratoma
- Substernal goiter
- Thymic hyperplasia
- Thymic cyst
- Mesenchymal tumors

##### MIDDLE MEDIASTINUM

- Lymphoma
- Tuberculosis
- Sarcoidosis
- Histoplasmosis
- Castleman disease
- Bronchogenic cyst
- Sarcoma

##### POSTERIOR MEDIASTINUM

- Neuroblastoma
- Ganglioneuroma
- Neurofibroma
- Primitive neuroectodermal tumor
- Sarcoma
- Germ cell tumor
- Schwannoma
- Duplication cyst

Unusual causes, such as hyperthyroidism and Addison disease, also should be included in the differential diagnosis of generalized adenopathy.

### ASSESSMENT

The evaluation of lymphadenopathy is summarized in Table 175-4 and discussed in detail below.

#### History, Physical Examination, and Chest Imaging

The history and physical examination may reveal a source of a localized infection, such as a dental abscess, mastoiditis, scalp infection, insect bite, or cat scratch. Alternatively, systemic diseases, such as infectious mononucleosis, juvenile idiopathic arthritis, and infection with the human immunodeficiency virus, may be suggested by other characteristic historical and physical findings. The physical examination should include all the palpable nodes (see Table 175-1). Furthermore, assessment of enlarged lymph nodes that have no obvious inflammatory explanation requires a chest radiograph or computed tomography (CT) scan to determine whether enlarged mediastinal or hilar nodes are present. The chest radiograph is the study most commonly omitted in evaluating patients who have lymphadenopathy; the identification of mediastinal or hilar adenopathy would preclude trials of antibiotics, which often delay a diagnostic biopsy.

#### Imaging

The abdominal lymph nodes, including retroperitoneal, periportal, and celiac nodes, as well as the nodes of the splenic hilum, are difficult to evaluate without sophisticated imaging techniques. The spleen, which is primarily lymphoid tissue, may be enlarged in infectious, immunologic, and neoplastic disorders and may be delineated by ultrasound or CT examination. Abdominal and pelvic lymph nodes may be visualized by ultrasonography or may require techniques such as CT and magnetic resonance imaging. The sensitivity and specificity of methods to define chest (mediastinal or hilar) lymphadenopathy are variable. In one study of patients thought to have tuberculosis, the chest radiograph was 67% sensitive and 59% specific compared with spiral chest CT with contrast. Newer techniques include positron emission tomography and scintigraphy.

#### Complete Blood Cell Count and Acute Phase Reactants

A complete blood cell count may reveal the reactive lymphocytes of infectious mononucleosis or a granulocytosis with a shift to the left, suggesting systemic bacterial infection. Bicytopenia (eg, anemia, granulocytopenia, thrombocytopenia) would be a red flag that a hematologic malignancy, such as leukemia or lymphoma, or a metastatic disease involving the bone marrow, such as neuroblastoma, may underlie the lymphadenopathy. The finding of nucleated erythrocytes and immature granulocytes (leukoerythroblastic blood picture) on the blood film is an ominous sign suggesting bone marrow irritation, with premature release of blood cell precursors. This finding may be seen in metastatic diseases such as neuroblastoma

Table 175-4 Evaluation of Lymphadenopathy

and rhabdomyosarcoma, with immunologic vasculitis and with granulomas (mycobacteria) in the marrow. Isolated leukopenia and neutropenia may also be seen with viral infections or severe bacterial infections (particularly in infants). Other studies may be useful in assessing lymphadenopathy, including C-reactive protein and erythrocyte sedimentation rate, that detect a systemic inflammatory reaction and may reflect infection, vasculitis, or neoplasm.

### Infectious Evaluation

The diagnostic workup of potential infectious lymphadenopathy is diverse and depends on the history, the

patient's age, the location of the nodes (whether cervical, localized, or generalized), and the signs of inflammation accompanying the adenopathy. The cause of acute, inflamed, and localized adenopathy is often infectious and likely to be bacterial. A purified protein derivative or interferon- $\gamma$  release assay is indicated when tuberculosis is a possibility. Material should be obtained for culture and histologic or pathologic examination when possible, particularly in patients who do not respond to initial therapy. In children who have acute cervical adenitis, needle aspiration of an acutely inflamed, sometimes fluctuant, node demonstrates the infecting organism in two-thirds or more of

cases. In certain cases, a biopsy may be required. If tuberculosis or atypical mycobacterial infection is thought to be present (eg, young children with subacute lymphadenopathy in the submandibular or submental regions), then needle aspiration should be avoided to prevent spread of the infection; excisional biopsy is required. The material obtained from biopsy or aspiration should be cultured aerobically and anaerobically and examined histologically, including special stains such as that for cat-scratch disease (Warthin-Starry silver stain). Specific diagnosis by serologic assessment, antigen detection, polymerase chain reaction, and culture is available for most of the common agents causing lymphadenopathy in children (most prominently serology for *B. Henselae* [cat-scratch disease]). The erythrocyte sedimentation rate or the C-reactive protein may be useful in assessing underlying inflammation, but both may be elevated in immunologic and neoplastic diseases as well.

After initial evaluation by history, physical examination, chest radiograph, and preliminary laboratory studies, the physician may not yet have an obvious explanation for the node enlargement. If a bacterial source for localized adenopathy (eg, pharyngitis, cervical nodes) is suggested, then a limited course of 7 to 10 days of antibiotic therapy may be tried. However, if the nodes have not regressed significantly, then prompt further evaluation is necessary. At this time, a chest radiograph should be obtained if it has not already been performed. Hilar or mediastinal adenopathy requires prompt assessment of neoplastic or granulomatous causes. Even in the absence of mediastinal or hilar adenopathy, prompt biopsy of significantly enlarged, unexplained lymph nodes should permit institution of appropriate therapy.

### Biopsy

Biopsy of significant adenopathy should be performed early if no evidence of infection or other cause exists and particularly if mediastinal or hilar nodes are enlarged. The biopsy should encompass the central mass of the enlarged nodes so that a misdiagnosis of reactive inflammation in adjacent nodes can be avoided. This circumstance is particularly common in Hodgkin disease, in which an adjacent smaller lymph node may be more accessible and technically easier to biopsy but may not demonstrate the presence of Reed-Sternberg cells. Fine-needle aspiration is not recommended for biopsy of superficial, accessible nodes, although it might be useful for intrathoracic nodes to avoid thoracotomy. Appropriate expertise is required for interpretation, and negative findings are not definitive. For subacute, submandibular, or submental lymphadenopathy in which atypical mycobacteria are suspected, complete excisional biopsy provides both diagnosis and therapy.

Mediastinal adenopathy may be associated with airway or vascular obstruction (superior vena cava syndrome), presenting a critical risk if anesthesia or sedation is administered and a major dilemma in establishing a diagnosis.

Any biopsy should be performed at a medical center that specializes in the care of children so that all appropriate touch preparations, cultures, special cytochemical

or immunologic stains, flow cytometry, and biochemical, cytogenetic, and DNA studies are obtained. The pathology of Hodgkin disease, lymphoma, and other similar round-cell tumors may be difficult to establish and requires the assessment of a pediatric pathologist who has experience in these diseases. Immunophenotyping, cytogenetic analysis, molecular studies of gene rearrangement, and electron microscopy may be required for precise diagnosis. These studies, in conjunction with the histopathologic assessment, are central to the assessment and subsequent management, which may involve complex treatment with surgery, radiation, chemotherapy, or immunotherapy.

## TREATMENT

### Infectious Diseases (Details of Treatment—See Specific Organism)

Therapy of lymphadenitis depends on determining its cause or the most likely cause. Acute adenitis, particularly of the cervical area in young children, is frequently associated with infection from group A  $\beta$ -hemolytic streptococci or *Staphylococcus aureus*. The latter is particularly likely in adenitis that progresses to fluctuance. In the neonate and rarely in older children, group B streptococci may cause localized adenitis with or without cellulitis. In children beyond the neonatal period who have acute localized adenitis, particularly cervical adenitis, therapy should be initiated with an antibiotic directed at group A streptococci and penicillinase-producing strains of *S aureus* (eg, amoxicillin-clavulanic acid or cephalexin). Recently, infections with community-acquired methicillin-resistant *S aureus* in some areas have increased dramatically in children with skin and localized infections. In such circumstances, treatment should include an antibiotic to cover methicillin-resistant *S aureus* (eg, clindamycin or trimethoprim-sulfamethoxazole). For most patients, oral therapy is adequate.

The usual course of therapy is 10 to 14 days, but therapy should be continued for at least 5 days after the signs of acute inflammation have subsided. For patients who have suppurative adenitis from these organisms, drainage is not only diagnostic (by culturing the exudate obtained), but also therapeutic. A few patients may not respond to oral therapy, even with a drug to which the organism is sensitive. Parenteral antibiotic therapy then is required.

If an anaerobic infection is thought to be present, then therapy depends, in part, on the location of the adenitis, the type of organism, and the severity of the illness. Most anaerobic infections of the cervical and submental areas are serious infections associated with mouth flora, requiring inpatient therapy with clindamycin or metronidazole, possibly in combination with third-generation cephalosporins.

Both *M tuberculosis* and atypical mycobacteria can cause adenitis, with the latter being more frequent in children. Differentiating these may be difficult but is important because many strains of atypical mycobacteria are resistant to the usual antitubercular chemotherapy, and excisional biopsy may be required. If tubercular infection is thought to be present, then appropriate therapy for *M tuberculosis* should be initiated while awaiting

identification and sensitivities of the organism. Adenitis that is thought to be tubercular should not be incised or drained.

Cat-scratch adenitis is usually self-limited and generally requires no specific therapy. The discovery of *Bartonella* species, especially *B. henselae*, as the prime cause of cat-scratch disease has raised the possibility for specific antibiotic therapy, and some antibiotics alone or combined, including azithromycin, rifampin, and doxycycline, may be of clinical benefit. If nodes become markedly enlarged, tender, and fluctuant, then aspiration may help relieve symptoms; incision and drainage, however, should be avoided.

For the unusual case of severe primary herpes simplex virus infection with localized adenitis, treatment with oral acyclovir has shortened the clinical course.

### Neoplastic Disease

The treatment of neoplastic diseases today is, in most instances, oriented toward cure, with the effectiveness of therapy for lymphocytic and myelocytic leukemia, lymphomas, and Wilms and other tumors having improved markedly. The specific treatment of childhood cancer often involves combinations of chemotherapy, radiation therapy, and surgery, all of which depend on the individual diagnosis and are beyond the scope of this presentation. However, prompt, accurate diagnosis is essential for instituting specific treatment and optimal care of these patients.

#### WHEN TO REFER

- History and physical examination do not suggest an infectious cause.
- Potentially infectious nodes have not responded to a course of antibiotics.
- Supraclavicular, mediastinal, or hilar adenopathy is present.
- A biopsy is considered; biopsies should be performed only at a center specializing in the care of children.

#### WHEN TO ADMIT

- Biopsy requires hospitalization—for example, supraclavicular, mediastinal, or hilar biopsy.
- Biopsy results require inpatient treatment or further evaluation.
- An infection requires intravenous therapy.

## Chapter 176 MACROCEPHALY

Oscar H. Purugganan, MD, MPH

### DEFINITION

Macrocephaly is defined as a head circumference of more than 2 standard deviations above the mean (about the 97th percentile) based on age and gender. Head circumference values should be plotted in appropriate head circumference charts (see Chapter 178, Microcephaly), such as the Centers for Disease Control and Prevention (CDC) growth charts (for children 0–3 years). For children older than 3 years, the Nellhaus charts had been used previously, although new age- and sex-appropriate US charts were published in 2010.

### DIFFERENTIAL DIAGNOSES

Head size is influenced by the different components that make up the cranial cavity. Among the causes of a large head in children are hydrocephalus, an enlarged brain (*megalecephaly*), a thickened skull, and space-occupying lesions. These conditions are not mutually exclusive, and some children may have more than 1 underlying factor (Box 176-1).

#### Hydrocephalus

Hydrocephalus, an enlargement of the ventricular system, may be congenital or acquired. The clinical presentation is influenced by the age of onset and the underlying condition causing the hydrocephalus. An enlarging head circumference is the most obvious finding in an infant whose cranial sutures have not fused. In the older child whose sutures have fused, significant head enlargement does not occur, but other signs and symptoms of increased intracranial pressure, such as headaches, vomiting, and papilledema, may occur.

Conventionally, hydrocephalus has been classified as either communicating or noncommunicating, depending on whether the connection between the ventricular system and the subarachnoid space is intact. Communicating hydrocephalus results from either the impaired absorption of cerebrospinal fluid by the arachnoid villi (from meningeal irritation caused by meningitis, trauma, or malignant infiltration) or less commonly with overproduction of cerebrospinal fluid from a choroid plexus papilloma. Noncommunicating or obstructive hydrocephalus is marked by enlargement of the ventricular system proximal to the site of an obstruction. The obstruction may be an anatomic defect, such as aqueductal stenosis, or the result of a tumor, infection, or infiltrate. In many cases, however, the classification of hydrocephalus as either communicating or noncommunicating may not be clear-cut; common causes of hydrocephalus, such as intraventricular hemorrhage and intrauterine infections, may lead to both communicating and noncommunicating hydrocephalus.

**BOX 176-1 Causes of Macrocephaly****HYDROCEPHALUS**

- Intraventricular hemorrhage
- Meningomyelocele
- Dandy Walker malformation
- Aqueductal stenosis
- Malignancy
- Intrauterine infections
- Meningitis

- Fragile X syndrome
- Various other genetic syndromes

***Megalencephaly—idiopathic (benign)*****SKULL THICKENING AND SKULL ABNORMALITIES**

- Thalassemia
- Cleidocranial dysostosis and other skeletal disorders

**SPACE-OCCUPYING LESIONS**

- Vascular malformations
- Intracranial tumors
- Subdural effusion
- Subdural hematoma

Intraventricular hemorrhage occurs in about 15% of premature infants with birth weight less than 1,500 g. The severity of hemorrhage is graded as follows:

- Grade I: subependymal hemorrhage
- Grade II: intraventricular hemorrhage without ventricular dilation
- Grade III: intraventricular hemorrhage with ventricular dilation
- Grade IV: intraventricular and intraparenchymal hemorrhage

Although subtle changes in head circumference may be present, macrocephaly is not always evident in an infant with intraventricular hemorrhage. Grade III and IV hemorrhages are associated with poorer neurodevelopmental outcomes than grades I and II, with an estimated 35% and 90% of affected children, respectively, showing neurologic sequelae.

Hydrocephalus with Chiari type II defect is present in 80% of children with myelomeningocele. Macrocephaly is commonly the first manifestation of the Dandy Walker malformation, a cystic dilation of the fourth ventricle, with hypoplasia of the cerebellar vermis and a variety of other cranial malformations. Head size may be normal at birth, but acceleration in head growth is noted in most children by 1 year of age, sometimes with prominence of the posterior part of the skull.

Congenital aqueductal stenosis, which may occur sporadically or be transmitted by X-linked inheritance, causes severe hydrocephalus that may complicate labor and delivery with cephalopelvic disproportion and lead to signs and symptoms of increased intracranial pressure after birth.

A condition characterized by a benign accumulation of extracranial fluid, probably subarachnoid, is identified in many children with macrocephaly who have an unremarkable neurologic examination. The exact nature of the extracranial collection has not been clearly established, leading to problems with nomenclature; the condition is variously referred to, whether accurately or inaccurately, as benign macrocephaly, external hydrocephalus, benign extracerebral fluid collections, benign subdural collections, and benign enlargement of the subarachnoid space. Neuroimaging reveals an extracerebral fluid collection most evident in the prefrontal area and, in some cases, mild nonprogressive dilation of the ventricular system. The size of the brain is normal. Affected children may have normal or large head circumferences at birth. In the succeeding months, the head circumference grows to greater than the 98th percentile and then generally parallels the normal growth curves. The large head size is an isolated feature, and the affected child has an otherwise normal neurologic examination and age-appropriate development, although transient early developmental delays, especially in the first year of life, may be observed. The condition seems to be self-limited, with normalization of computed tomography scan findings usually by 2½ years of age. The relationship of this condition to benign megalencephaly, wherein the brain is large but no extracranial fluid accumulation is present in a child who is also neurologically intact, has not been established and is not fully understood. More recently, an association with subdural hematoma in infancy has been suggested.

**Megalencephaly**

Another common cause of macrocephaly is an enlargement of the brain. Traditionally, megalencephaly is classified as metabolic or anatomic. In metabolic megalencephaly, enlargement of the brain is caused by an inborn error of metabolism that leads to the abnormal deposition of some substrate in the brain. The head circumference is usually normal at birth and then enlarges and may cross percentiles over time. It coincides with significant developmental delays and psychomotor regression. Most of these inborn errors are autosomal recessive disorders. The mucopolysaccharidoses, leukodystrophies such as Canavan disease and Alexander disease, are examples of metabolic conditions causing macrocephaly.

In Hurler syndrome, the most severe form of mucopolysaccharidosis resulting from a deficiency of  $\alpha$ -L-iduronidase, an enlarging head may be noted to cross percentiles during infancy. Coarse facial features, frontal bossing, and corneal clouding are characteristic findings of the syndrome. In the infantile form of Canavan disease, a leukodystrophy that predominantly affects Ashkenazi Jews from a deficiency of aspartoacylase, macrocephaly is associated with irritability, poor visual fixation, head lag, and motor delay, which are noted in the first few months of life. Alexander disease is a rare, mostly sporadic condition characterized by abundant accumulation of glial fibrillary acidic protein in Rosenthal fibers. Affected infants exhibit macrocephaly, seizures, spasticity, and developmental regression.

In anatomic megalencephaly, the large head size is usually present at birth and is often associated with neurodevelopmental impairment. The brain is abnormally large because of an increase in the size and number of its cells. The Online Mendelian Inheritance in Man (OMIM) provides a comprehensive list of syndromes associated with macrocephaly and megalencephaly. In overgrowth syndromes, macrocephaly is usually present at birth as part of a generalized increase in body size. An example is Sotos syndrome, which is associated with facial dysmorphism, neurodevelopmental deficits such as poor coordination and cognitive and behavioral problems, and macrocephaly that may result from a combination of megalencephaly, ventricular enlargement, and midline anomalies. It has been reported that about 90% of clinical cases of Sotos syndrome have mutations or deletions involving the *NSD1* gene in chromosome 5q35. Neurocutaneous syndromes such as neurofibromatosis, tuberous sclerosis, and hypomelanosis of Ito are associated with megalencephaly in addition to characteristic skin findings, intracranial conditions, and neurodevelopmental problems. In achondroplasia, megalencephaly is present in a child with short stature, shortened proximal arms and legs (rhizomelia), and dysmorphic facial features. Affected individuals usually have normal intelligence but are at risk for hydrocephalus, obstructive sleep apnea or central apnea, and spine and joint problems. Compared with the general population, a disproportionately large number of autistic children have enlarged head circumferences. The pattern of brain growth in some autistic children seems to be abnormal, with acceleration of head growth in early childhood, hyperplasia in cerebral gray matter and cerebral and cerebellar white matter, and a slight decrease in brain volume during adolescence. Whether this acceleration in head growth in early childhood relates to the behavioral and developmental features of autism remains unclear. Mutations in the phosphatase and tensin homolog (*PTEN*) gene, which have been associated with a spectrum of disorders with a predisposition to hamartomas and certain cancers such as Cowden syndrome, Bannayan-Riley-Ruvalcaba syndrome, and Proteus syndrome, have been identified in some autistic children with severe macrocephaly. Fragile X syndrome is associated with a constellation of physical findings, including macrocephaly, a longish face with

prominent ears, joint hyperextensibility, and enlarged testes. A family history on the mother's side of intellectual disability, developmental and behavioral problems, and autistic behaviors suggests the possibility of this X-linked disorder.

A child with a large head who has no significant collection of extraventricular or intraventricular fluid, a normal neurologic examination and developmental history, no signs of raised intracranial pressure, and a family history of large head sizes in normal adults can be considered to have benign or idiopathic megalencephaly. Although these individuals have been thought to develop normally, recent evidence suggests they may exhibit mild neurodevelopmental dysfunction such as incoordination and visual-motor weaknesses.

### Other Causes of Macrocephaly

Thickening of the skull is a rare cause of macrocephaly. Children with a hemolytic anemia, such as  $\beta$ -thalassemia, may exhibit frontal bossing attributable to extracranial hematopoiesis in their skull bones. Cleidocranial dysostosis is an autosomal disorder of abnormal bone formation characterized by delayed closure of fontanelles, widening of the head circumference, and other skeletal abnormalities. Space-occupying lesions, such as an arteriovenous malformation or a brain tumor, may also produce macrocephaly. Although usually asymptomatic, subdural effusion is a complication of bacterial meningitis that may produce an enlarging head circumference, bulging anterior fontanelle, and signs of increased intracranial pressure in infants. Subdural hematoma may present with macrocephaly in infants but is usually associated with other symptoms as well.

## EVALUATION

### Relevant History

A review of previously measured head circumferences can ascertain whether a child has had any change in the pattern or percentiles of head circumference over time. A large head circumference at birth presupposes a cause of prenatal origin, necessitates a detailed prenatal history, and may indicate anatomic megalencephaly. Conditions that may cause congenital macrocephaly include X-linked aqueductal stenosis and the overgrowth syndromes. An abnormally enlarging head postnatally in a child with neurodevelopmental problems is a clue to an acquired condition, such as acquired hydrocephalus or a possible metabolic disorder. The history should explore delays in the developmental milestones; regression in motor, language, and social skills; seizures; and signs of increased intracranial pressure such as lethargy, vomiting, and behavioral changes. A family history of any genetic, neurologic, and developmental condition may be a red flag for similar disorders, whereas a history of otherwise normal parents and siblings with large heads can be reassuring.

### Physical Examination

The physical examination of the child with macrocephaly should focus on the specific issues listed in Box 176-2.

### BOX 176-2 Physical Examination of a Child with Macrocephaly

- Accurate measurement of the head circumference and assessment of the pattern of head growth
- Inspection and palpation of the skull
- Comparison of the head circumference with other growth parameters
- Presence or absence of dysmorphic features
- Presence or absence of congenital abnormalities involving other organ systems
- Thorough neurologic and developmental assessment, including a check for signs of increased intracranial pressure
- Skin examination using Wood lamp

Monitoring of head size must be performed periodically during health care maintenance visits. In the presence of a rapid enlargement in head circumference, more frequent monitoring, at the very least, is necessary. Measurements should be plotted on the appropriate head circumference charts. A disproportionately enlarged head in relation to height and weight may indicate a primary neurologic disorder. Measuring the size of the fontanelles and palpating sutures are important. Significant hydrocephalus in infants may produce a bulging anterior fontanelle and separation of cranial sutures, which are uncommon in anatomic megalencephaly. A vein of Galen arteriovenous malformation may produce a cranial bruit on auscultation. Because macrocephaly is a feature of many genetic syndromes, dysmorphic features and other organ involvement should be noted. Examination of the skin may reveal café au lait spots, axillary freckling, ash-leaf spots, and a whorled pattern of pigmentation that may indicate a neurocutaneous disorder. Careful neurologic examination is critical and may reveal abnormalities in muscle tone and posture, asymmetries, persistence of primitive reflexes, and hyperreflexia. Developmental assessment may reveal cognitive impairment, autistic features, learning disabilities, or behavioral difficulties. It is also important to measure the head circumference of the parents and make note of any dysmorphic features they may have.

#### Laboratory Testing

Metabolic testing is available to identify many of the storage diseases and is recommended in a child exhibiting developmental regression. Genetic testing should be done as appropriate for the clinical assessment.

#### Imaging

Neuroimaging is the procedure of choice in evaluating macrocephaly. For infants with open fontanelles, head ultrasound is useful in identifying intraventricular hemorrhage, hydrocephalus, and intracranial tumors. This procedure is especially useful in

infants because it eliminates the need for sedation. Computed tomography can identify hydrocephalus, intracranial calcifications, and hemorrhages. Magnetic resonance imaging (MRI) is most informative, especially in identifying gray and white matter disease (eg, leukodystrophy), migration defects, hydrocephalus, and posterior fossa lesions. MRI is also helpful in studying the subtleties in subdural and subarachnoid hemorrhages. Consultation with a neurologist or radiologist may be helpful in deciding which procedure would be most appropriate. MRI is generally not indicated in patients with autism and macrocephaly unless there are other concerns not explained by autism (eg, focal neurologic findings, cranial nerve dysfunction, severe headache). A skeletal survey may reveal bone age abnormalities in the overgrowth syndromes and radiologic abnormalities that may be present in the mucopolysaccharidoses, bone dysplasias, or trauma.

#### Management

The management of macrocephaly depends on its cause. Shunting procedures are the treatment of choice for significant and progressive hydrocephalus; however, shunt infection, obstruction, and malfunction are not rare and continue to be challenges in the care of these children. In premature infants, the risk for complications is even greater; medical management with pharmacologic agents (carbonic anhydrase inhibitors or other diuretics) and serial lumbar punctures may be used as initial therapy. Medical management is also used in asymptomatic or minimally symptomatic patients with slowly progressive hydrocephalus. For Dandy Walker cysts, shunting has been recommended to drain the hydrocephalus or the posterior fossa cyst, or both. Children in whom inborn errors of metabolism are suspected should be referred for genetic evaluation, treatment, and counseling. Although the treatment for these conditions is mainly supportive and symptomatic, bone marrow transplantation and enzyme replacement therapy are promising interventions for certain disorders. Although no specific treatment is available for anatomic megalencephaly, pediatricians should be aware of the association with developmental and cognitive problems, which warrant early intervention and special education services. The presence of subdural hematoma requires further evaluation (eg, skeletal survey, retinal examination) and may include referral to a child abuse expert. Serial measurement of the head circumference and clinical assessments are generally all that are needed for benign accumulation of extracranial fluid and idiopathic megalencephaly.

#### WHEN TO REFER

- Head circumference of more than 2 standard deviations above the mean (especially 3 standard deviations above the mean)
- Head circumference that is crossing percentiles or rapidly growing
- Dysmorphic features
- Abnormal neurologic examination

- Regression in developmental skills or significant developmental delay
- Suspected child abuse

### WHEN TO ADMIT

- Signs of increased intracranial pressure or mental status change
- Shunt infection or malfunction

## Chapter 177

# MEDICALLY UNEXPLAINED SYMPTOMS

Rebecca Baum, MD; John Campo, MD

### BACKGROUND

Medically unexplained symptoms (MUS) can present significant challenges and frustrations to the children affected by them, their families, and the physicians involved in their care. While medically unexplained physical symptoms are often associated with mental health issues, children with MUS often present in primary care and general medical settings rather than the mental health setting. Patients with MUS often present for multiple office visits and are at risk for potentially dangerous and unnecessary evaluations, laboratory tests, and procedures. Patients and families may be frustrated and confused by the physician's

judgment that "nothing is wrong" despite continued pain and impairment. MUS are thus an important entity for physicians to recognize to help facilitate accurate assessment and intervention.

Historically, physicians have been trained in the biomedical model that explains the presence of physical symptoms with a diagnosis based on the presence of pathology consistent with a specific disease. In this model, unexplained symptoms may not be presumed to be real, or may be considered representative of a mental disorder. This dichotomous approach, termed *dualism*, distinguishes between physical and mental disorders by virtue of whether there is evidence of a biomedical explanation. It is increasingly being recognized that such dualistic thinking is inadequate to address the entity of MUS. Using this model, physicians may complicate care, or even put patients at risk, in an attempt to avoid "missing" explanatory physical disease. Families and patients may feel stigmatized, misunderstood, and lacking in an explanation for their symptoms.

Our current understanding of pain suggests that it is an unpleasant sensory and emotional experience representative of physiologic changes and tissue damage. This suggests that pain is a derivative of demonstrable tissue pathology, yet pain can also be experienced subjectively in the absence of demonstrable pathology. Similarly, the level of pain experienced in association with a given degree of tissue damage may also vary. Rather than focusing on false dichotomies between physical and psychological health, it is preferable to recognize the connection between psychology and physiology. The term *somatization* is used to reflect the experience of the individual, including his subjective experience, distress, and desire to seek medical care, in the setting of MUS.

### EPIDEMIOLOGY

Medically unexplained symptoms are often encountered across childhood and adolescence, with pain and fatigue being especially common in all age groups. It is also important to remember that the presence of 1 type of MUS typically predicts the presence of other MUS. In preschool children, abdominal pain is a common manifestation. Among children and adolescents, headache and abdominal pain are the most prevalent symptoms, though other types of pain, such as limb and chest pain, are often reported. Fatigue is a particularly common complaint in teens. Other symptoms include urinary, cardiovascular, rheumatologic, and gastrointestinal complaints. MUS suggesting neurologic or sensory impairment, often referred to as "conversion" symptoms, are relatively unusual in community settings yet more common in specialty settings. A study of teens in the Ontario Child Health Study suggested a prevalence of recurrent somatic symptoms in the primary care setting of 4% for boys and 11% for girls. Other studies report that between 2% and 20% of children in primary care present with MUS. Boys and girls may have different clinical presentations, with some studies suggesting that girls report more somatic symptoms than boys and more frequently report symptoms of headache or abdominal pain than boys, particularly with increasing age into adolescence. All types of MUS

can be associated with significant impairment for patients and their families. This includes missed school days, increased health care utilization, distress, patient suffering, limitation of activities, impaired peer interactions, and significant effect on family functioning.

The precise etiology of MUS is unknown. Certain associations and risk factors have been identified (Box 177-1). In general, children with emotional and behavioral problems are more likely to experience MUS than otherwise healthy children. In a primary care sample, children identified as somatizers had a higher frequency of emotional/behavioral problems, including internalizing symptoms such as worrying, fear of new situations, and problems with separation. Children with diagnosed mental health disorders such as anxiety, depression, and disruptive behavior disorders have also been found to exhibit more somatic symptoms, including headache, abdominal pain, and musculoskeletal pain.

## CLASSIFICATION

Definitions for conditions characterized by chronic pain and physical suffering are detailed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)*, under the category of Somatic Symptom and Related Disorders. This category replaces that of Somatoform Disorders in *DSM-IV*. These disorders are characterized by pain or other somatic symptoms in association with impairment in functioning and significant individual distress. Somatic Symptom Disorder (SSD) is the diagnosis applied in the presence of distressing or impairing somatic symptoms along with excessive, maladaptive, or disproportionate thoughts or feelings about the physical symptoms. See Table 177-1 for additional disorders in this category, including Illness Anxiety Disorder, which replaces hypochondriasis, Conversion Disorder, and Psychological Factors Affecting Medical Condition.

### BOX 177-1 Risk Factors for the Development of Medically Unexplained Symptoms

- Genetics
- Modeling
- Physical illness
- School stressors
- Family stressors
- High-achieving families
- Parental overprotection
- Secondary gain<sup>a</sup>
- Impaired or limited coping mechanisms
- Difficulty identifying/expressing feelings
- Difficulty with transitions
- Psychiatric comorbidity
- Trauma

<sup>a</sup>Secondary gain refers to the social and familial reinforcement of the symptom.

Derived from Ibeziako P, Bujoreanu S. Approach to psychosomatic illness in adolescents. *Curr Opin Pediatr*. 2011;23:384–389.

Factitious Disorder, defined by the intentional falsification of symptoms with the apparent goal of achieving behavioral and social benefits associated with the sick role, is now included in this category as well. Historically, these disorders were considered when a medical explanation could not be found, although, in many cases, it can be difficult and counterproductive to fully exclude an exhaustive list of potential medical conditions. In *DSM-5*, the key component of these disorders is the presence of somatic symptoms and the way they are interpreted by the patient, rather than solely by the lack of medical explanation. Children with these disorders experience significant impairment across 1 or several domains, including relationships with peers or parents, school functioning, and participation in extracurricular activities. Table 177-1 describes the categories of somatic symptom and related disorders according to *DSM-5*, with the same criteria applied to both adults and children.

When considering the presence of a somatic disorder, it is important to assess for physical disorders that may be causing or contributing to the child's symptoms. However, the physician is cautioned to avoid unnecessary testing once it can be reasonably assumed that a medical disorder has been excluded, which can present a challenge for physicians. It is recommended that somatic disorders be included in the differential diagnosis rather than relegated to a diagnosis of exclusion. Other conditions to include in the differential diagnosis of MUS include Psychological Factors Affecting Other Medical Conditions, which describes the presence of psychological factors and symptoms associated with an underlying medical condition. Conditions such as anxiety and depression may also result in pain and fatigue and thus should be considered the primary diagnosis in those circumstances.

## ASSESSMENT

An empathetic and collaborative approach is recommended when considering MUS. Children affected by MUS and their families may be frustrated by frequent office visits, multiple laboratory tests, and being told that “nothing is wrong” despite patient suffering. While the approach to each child should be individualized, general principles can help guide successful assessment. Important aspects to consider during the assessment process are presented in Box 177-2. MUS should be approached just as any other symptom in the pediatric history, with a review of symptom characteristics including duration, frequency, intensity, and moderating factors. Special attention should be paid to environmental stressors, opportunities for secondary gain, and emotional factors such as anxiety, depression, or other psychological symptoms.

In addition to a careful history, standardized tools can be helpful in the assessment process. The Children's Somatization Inventory (CSI) can be used to assess for the presence of multiple somatic symptoms. It has been revised to a 24-item questionnaire that includes parent and child (age  $\geq 7$ ) versions and is available in the public domain. The Functional Disability Inventory is a 15-item questionnaire with parent and child (age  $\geq 8$ ) versions that can be used to assess health status across multiple domains.

**Table 177-1** Classification of Somatic Symptom and Related Disorders

DISORDER	DESCRIPTION
Somatic Symptom Disorder	<ul style="list-style-type: none"> <li>• Presence of <math>\geq 1</math> somatic symptoms that are distressing or result in significant disruption of daily life.</li> <li>• Excessive thoughts, feelings, or behaviors related to the somatic symptoms.</li> </ul>
Illness Anxiety Disorder	<ul style="list-style-type: none"> <li>• Symptoms must be persistent (usually <math>&gt;6</math> months).</li> <li>• Preoccupation with having a serious illness (<math>\geq 6</math> months).</li> <li>• If a medical condition or strong family history is present, worry is out of proportion to the likelihood of severe illness; somatic symptoms, if present, are mild.</li> <li>• High degree of anxiety about one's health.</li> <li>• Excessive engagement in health-related behavior or avoidance of necessary health care.</li> </ul>
Conversion Disorder	<ul style="list-style-type: none"> <li>• Presence of <math>\geq 1</math> symptoms of altered voluntary motor or sensory function that result in significant distress or impairment.</li> <li>• Evaluation suggests that symptoms are incompatible with recognized medical conditions.</li> </ul>
Psychological Factors Affecting Other Medical Conditions	<ul style="list-style-type: none"> <li>• Presence of psychological or behavioral factors that result in delayed recovery or added health risk, interfere with treatment, or escalate the need for medical treatment.</li> </ul>
Factitious Disorder (Imposed on Self or Imposed on Another)	<ul style="list-style-type: none"> <li>• An underlying medical condition must be present.</li> <li>• Intentional falsification of physical or psychological signs or symptoms or infliction of injury.</li> <li>• Deceptive behavior is present.</li> </ul>
Other Specified Somatic Symptom and Related Disorder	<ul style="list-style-type: none"> <li>• Presence of somatic symptoms that cause significant distress or impairment but do not meet full criteria for another category of somatic symptom and related disorders.</li> <li>• May be used when symptoms are brief (eg, 6 months) or just below the diagnostic criteria.</li> </ul>
Unspecified Somatic Symptom and Related Disorder	<ul style="list-style-type: none"> <li>• Presence of somatic symptoms that cause significant distress or impairment but do not meet full criteria for another category of somatic symptom and related disorders.</li> <li>• Used only in unusual situations when there is insufficient information to make a more specific diagnosis.</li> </ul>

### **BOX 177-2** Important Principles in the Assessment of Children With Medically Unexplained Symptoms

- Acknowledge symptoms, patient experience, and family concerns.
- Review past evaluations and treatment.
- Investigate fears related to symptoms.
- Remain alert to unrecognized medical diagnosis.
- Avoid unnecessary tests.
- Avoid diagnosis by exclusion.
- Understand symptom timing, context, and characteristics.

Adapted from Campo JV, Fritz G. A management model for pediatric somatization. *Psychosomatics*. 2001;42:467–476.

## **MANAGEMENT**

Collaborative care in the management of MUS requires communicating diagnostic impressions to the family in a clear and honest manner. Families may benefit from a discussion of the interplay between physiologic and emotional factors, with reassurance that the absence of diagnosable medical disease does not minimize the child's suffering or negate the reality of the problem. Physicians should be mindful of the stigma associated with mental health conditions and avoid the mind-body dualism that may characterize MUS as being "all in your head." The use of placebo and other forms of deception in attempts to achieve diagnosis or reduce symptoms is discouraged.

Once diagnostic impressions are communicated and questions are discussed, the physician must then attempt to shift the family's focus from the cause of symptoms to improving the child's functioning and reducing suffering. The physician should facilitate the

**Table 177-2** Interventions for Children With Somatic Disorders

INTERVENTION	CHARACTERISTICS
Cognitive behavioral therapy	May involve a combination of <ul style="list-style-type: none"> <li>• Cognitive restructuring (eg, “I realize I have some pain today, but I can still go for a walk with my friends.”)</li> <li>• Relaxation</li> <li>• Graded exposure to unpleasant experiences<sup>a</sup></li> </ul>
Rehabilitative approach	Focus on coping and improving health status
Behavioral intervention	Approaches include <ul style="list-style-type: none"> <li>• Reinforcement of healthy behaviors</li> <li>• Minimization of secondary gain</li> </ul>
Self-management	Possible techniques include mindfulness, hypnosis, imagery, and relaxation.
Family intervention	Involves work with the family system that may inadvertently reinforce the sick role
Maximal treatment of psychiatric comorbidities	Important to consider given the high prevalence of mental health conditions in children with medically unexplained symptoms
Medication management	Should be considered for <ul style="list-style-type: none"> <li>• The treatment of underlying mental health conditions</li> <li>• Somatic symptoms that accompany mental health conditions</li> </ul>

<sup>a</sup>Masia Warner C, Reigada LC, Fisher PH, et al. CBT for anxiety and associated somatic complaints in pediatric medical settings: an open pilot study. *J Clin Psychol Med Settings*. 2009;16(2):169–177.

Derived from Dell ML, Campo JV. Somatoform disorders in children and adolescents. *Psychiatr Clin North Am*. 2011;34:643–660.

development of a treatment plan that addresses physical pain, stress reduction, and reduction of stigma while fostering hope that the child will improve. Goals should be developed collaboratively and should be meaningful to the child and family. In many cases, treatment will involve an interprofessional approach involving medical, mental health, and allied health disciplines. Clear communication across disciplines is essential.

A number of interventions have been proposed for the treatment of somatic disorders, and thus MUS (Table 177-2). Treatments may be delivered independently or in combination, although medication is rarely successful if used without supportive therapies.

A substantial portion of the child’s treatment may occur outside the realm of primary care. In these circumstances, an important role for the pediatrician is one of care coordination, hope, and support. Pediatricians may be especially helpful in recognizing MUS as a possibility and making timely referrals to mental health professionals as indicated. In situations where symptoms are less intense or impairing, primary care management may be appropriate. In either case, pediatricians can play a key role in supporting families through the assessment and treatment process, which includes conveying an understanding that their concerns will be taken seriously and addressing parental anxiety, if present. Physicians in underserved areas may find themselves providing more direct care given challenges related to mental health and specialty care access. The psychiatric literature contains excellent resources for pediatricians who are interested in the assessment and initial management of MUS. In addition, a number of states are implementing psychiatric consultation resources for physicians that can provide guidance, education,

and, in some cases, facilitated referrals provided by Child and Adolescent Psychiatry. More information about these programs can be accessed through the National Network of Child Psychiatry Access Programs. Pediatricians should also be aware of their own frustration, as somatic disorders may present significant challenges in the primary care setting. Seeking advice and support from colleagues and specialists can be helpful in alleviating this frustration.

## PROGNOSIS

In general, the prognosis for children presenting with MUS is favorable, but proper symptom recognition and intervention are essential. An association has been documented between MUS in children and subsequent anxiety or depression in adulthood, as well as between anxiety and depression in childhood and subsequent impairing somatic symptoms in adulthood. Further studies will be needed to determine if identification and intervention in childhood can mitigate the development of lifelong symptoms. Meanwhile, it is clear that pediatricians play a key role in the initial management of the child with MUS, as well as in family support and care coordination. This type of approach can reduce child and family frustration, lead to improved outcomes, and be a rewarding experience for the physician who is able to help guide families through this complex process.

## Chapter 178 MICROCEPHALY

Oscar H. Purugganan, MD, MPH

### DEFINITION OF TERMS

Microcephaly refers to a head size that is 2 standard deviations below the mean (about the third percentile) based on age and gender. In itself, microcephaly means a small head; *micrencephaly* is the accurate term for a small brain. Because the forces of brain growth generally determine ultimate cranium size, a small brain leads to a small head. Without further brain growth, secondary closure of the sutures of the skull will ensue before the expected time, which should be differentiated from *craniosynostosis* in which primary and premature closure of sutures occurs with a normally growing brain.

### MEASUREMENT AND USE OF GROWTH CHARTS

Measuring the head circumference is an important element of the pediatric physical examination and should be performed at each well-child visit, especially in the first 3 years of life. Accurate measurements are critical and should be plotted on standardized charts. In the United States, the Centers for Disease Control and Prevention (CDC) released the latest growth charts in 2000. These charts, which include head circumference charts, were based on 5 national health surveys from 1963 to 1994 and have been updated from the 1977 growth charts. A new feature of these updated charts is the inclusion of curves for 3rd and 97th percentiles, which are important cutoffs in the measurements of head circumference. The World Health Organization (WHO) released new international growth charts for children up to 5 years of age in 2006. These charts represent growth standards derived from healthy children growing under optimal conditions from 6 sites worldwide. Their applicability in various clinical settings (including the US) and their potential effect on clinical practice are currently being investigated. Head circumferences of children

older than 3 years have traditionally been plotted on the growth curves developed by Nellhaus; newer US-normed head circumference charts from birth to 21 years were published in 2010. Charts are available for special populations with disturbances in growth, such as Down syndrome, Williams syndrome, achondroplasia, and very low birth weight.

Head circumference is measured by using a flexible, nonstretchable tape, running along the head above the supraorbital ridges and across the most prominent part of the occiput. This measurement is known as the occipitofrontal circumference and has been shown to correlate with brain volume. More instructive than a single measurement is a series of measurements over time, which can identify head circumferences that may be crossing percentiles while still falling within the normal range. Brain growth is maximal during the last few weeks of gestation to the first 2 years of life. Boys average a slightly larger head size than girls; the average head size at birth for boys in the United States is about 36 centimeters, and for girls about 35 centimeters.

### DIFFERENTIAL DIAGNOSIS

Microcephaly is a physical finding and not a diagnosis. A multitude of conditions exist that can lead to a small brain. These conditions can be either genetic or environmental (see Box 178-1). They can be syndromic or nonsyndromic.

Clinically, a useful approach to the evaluation of microcephaly is to determine whether the small head circumference is noted at birth (congenital microcephaly) or whether the head circumference does not grow as expected after birth (acquired microcephaly).

Congenital microcephaly (noted at birth) can be either from genetic or environmental causes.

Genetic microcephaly is almost always present at birth; Rett syndrome (see below) is a notable exception. In these conditions, the brain structure may be either normal or abnormal.

In microcephaly vera, or true microcephaly, the brain is very small, usually 3 standard deviations below the mean, but the brain architecture is grossly normal. Patients almost always have intellectual disability (ID) but have an otherwise unremarkable neurologic examination. A sloping forehead and prominent ears are usually the only dysmorphic features. Transmission is mainly autosomal recessive, although autosomal-dominant and X-linked forms also exist. Three genes that cause microcephaly vera have been identified: microcephalin (*MCPH*), abnormal spindle in microcephaly (*ASPM*), and deoxynucleotide carrier (*DNC*) protein, which is implicated in Amish microcephaly.

More common than microcephaly vera is a microcephalic child who has severe neurologic impairment such as seizures, spasticity, and global developmental delays. Neuroimaging may identify abnormal brain architecture such as defective prosencephalization (eg, holoprosencephaly), migration disorders (eg, lissencephaly, schizencephaly, pachygyri, polymicrogyri, heterotopias), and midline defects (eg, agenesis of corpus callosum).

Microcephaly may be associated with other clinical findings that collectively represent a genetic syndrome. Miller-Dieker syndrome, which is caused by a

**BOX 178-1 Causes of Microcephaly****GENETIC CAUSES**

- Microcephaly vera (isolated microcephaly with grossly normal brain architecture)
- Microcephaly with abnormal brain architecture (eg, lissencephaly, polymicrogyria)
- Genetic syndromes
  - Miller-Dieker lissencephaly
  - Seckel syndrome
  - Rubinstein-Taybi syndrome
  - Trisomy 21 syndrome
  - Trisomy 13 syndrome
  - de Lange syndrome
  - Rett syndrome
- Metabolic disorders
  - Aminoacidopathies
  - Mitochondrial
- Asymptomatic familial

**ENVIRONMENTAL CAUSES**

- Teratogens
  - Alcohol
  - Maternal phenylketonuria
  - Intrauterine irradiation
  - Other teratogenic drugs (eg, hydantoin)
- Intrauterine infections
- Maternal health problems
- Hypoxic-ischemic encephalopathy
- Traumatic brain injury
- Meningitis
- Malnutrition

deletion on the short arm of chromosome 17, is characterized by a small, smooth brain or lissencephaly (the most extreme of migration defects), facial dysmorphism, and severe ID. In Seckel syndrome, a rare autosomal-recessive disorder that has been mapped to loci in chromosomes 3 and 18, central nervous system (CNS) anomalies that suggest an underlying neuronal migration disorder are present together with growth retardation, intellectual disability, and a *bird-headed* facial appearance. Children with Rubinstein-Taybi syndrome have microcephaly, significant developmental problems, facial abnormalities, and broad thumbs and toes. Microdeletions of the cyclic adenosine monophosphate response element-binding protein gene on chromosome 16 have been implicated in this disorder. Trisomies account for some cases of microcephaly. A classic example is Down syndrome (trisomy 21 syndrome) in which microcephaly is part of the characteristic phenotype that includes distinct facial features, congenital heart anomalies, and growth retardation. In de Lange syndrome, affected children have growth retardation, microcephaly, hirsutism, and unusual facial features such as synophrys and low anterior hairline. Most cases are sporadic, but an autosomal dominant inheritance has been suggested.

*Smith's Recognizable Patterns of Human Malformation* and the online reference Online Mendelian Inheritance in Man (OMIM) provide comprehensive lists of conditions that are associated with abnormalities in head size.

Based on the definition of microcephaly, it follows that about 2.5% of all children would be classified as microcephalic, and, most certainly, some of these children will be neurologically normal, especially those with head sizes immediately below 2 standard deviations from the mean (head circumference  $>3$  standard deviations below the mean is almost always associated with some degree of neurologic impairment). In individuals with isolated microcephaly who are neurologically intact and have normal intelligence, measuring the head circumferences of the parents and siblings is important. A family history of small head size in the context of normal development and neurologic examination describes asymptomatic familial microcephaly.

Prenatal environmental factors may also lead to congenital microcephaly. A small head circumference at birth often reflects a condition of early prenatal origin. Intrauterine infections such as cytomegalovirus, toxoplasmosis, and rubella have been implicated in the development of microcephaly, and may also produce intrauterine growth retardation, hepatosplenomegaly, cardiac defects, retinopathy, cataracts, and hearing loss. Prenatal toxins that may lead to microcephaly in the newborn are alcohol, drugs of abuse such as cocaine, and irradiation. These environmental insults affect other organ systems as well, and microcephaly may be observed as a part of a syndrome. Prenatal exposure to alcohol may lead to intrauterine growth retardation, including microcephaly, facial features such as small palpebral fissures, smooth philtrum and thin upper lip, heart and eye defects, and behavioral and cognitive deficits, in a spectrum of disorders that range from alcohol-related neurodevelopmental disorder to fetal alcohol syndrome (FAS). Untreated maternal phenylketonuria and hyperphenylalaninemia produce findings very similar to those of FAS: microcephaly (the most consistent finding), ID, facial dysmorphism, and cardiac defects.

Head size that is not increasing as expected is a clue to an acquired microcephaly (also called postnatal-onset microcephaly), and investigation as to possible environmental and genetic causes should be initiated. Microcephaly from these causes is usually apparent by 2 years of age. A recent study classified 5 causal groups for acquired microcephaly: idiopathic, or no identifiable cause; familial; syndromic, with associated anomalies; symptomatic, following a pathogenic event; and mixed.

A genetic cause of microcephaly that does not usually present at birth is Rett syndrome, a condition exhibited almost exclusively in girls that is associated with a deceleration in head growth toward the second year of life leading to microcephaly, developmental regression, autistic features, and unusual hand mannerisms (hand-wringing and hand-washing movements). This genetic disorder has been mapped to the X chromosome and linked to a deletion of the *MeCP2* gene. Most cases are sporadic. Genetic causes also include metabolic disorders that may lead to a

deceleration of head growth in the first year of life; these conditions should be considered, especially if there is a history of parental consanguinity, episodic symptoms such as vomiting and encephalopathy, and developmental regression.

Severe perinatal asphyxia is an important environmental cause of acquired microcephaly. The asphyxiated newborn has a normal head circumference at birth, but head growth decelerates, and microcephaly and suboptimal head growth may be observed by 12 months of age, although acquired microcephaly can sometimes be detected as early as 6 weeks of age in infants who have had severe asphyxia. These children go on to develop significant neuromotor and cognitive deficits. Other environmental causes of acquired microcephaly are meningitis, malnutrition, traumatic brain injury, and abusive head trauma.

With multiple suture craniosynostosis, primarily a problem of the skull rather than the brain, the head circumference may be small at birth, or head growth may abruptly cease during infancy. The shape of the skull is asymmetrical, and evidence exists of bony ridging in the area of the fused sutures. Signs of increased intracranial pressure may be present. These characteristics clearly differentiate the microcephaly associated with craniosynostosis from *micrencephaly* in which the small head is round, symmetrical, smooth, and devoid of bony ridging in the area of the sutures. Premature closure of sutures may be an isolated feature or a part of a syndrome. Single-suture synostoses are not likely to cause microcephaly.

## EVALUATION

### Relevant History

Congenital microcephaly necessitates a thorough review of the prenatal history. Any potential exposure to toxins must be explored, such as the use of alcohol or other drugs of abuse. Poor maternal health during the pregnancy, intrauterine infections, and conditions causing placental insufficiency contribute to a suboptimal uterine environment that may lead to congenital microcephaly and intrauterine growth retardation. So, too, do psychosocial factors, as marked by lack of prenatal care and low levels of maternal education. A pedigree analysis can help identify a family history of genetic syndromes, miscarriages, or microcephaly. Taking note of the head sizes of the parents and siblings is an important component of the evaluation. A review of systems may identify medical problems such as feeding difficulties, seizures, and previous infections such as meningitis. The history should also include a chronology of developmental milestones, as well as a description of the child's current function and behavior, with close attention to possible developmental regression.

### Physical Examination

The physical examination of the microcephalic child should focus on the following:

1. Accurate measurement of the head circumference and assessment of the pattern of head growth and the onset of microcephaly if previous measurements are available

2. Inspection and palpation of the skull, looking for asymmetry and bony ridging
3. Comparison of the head circumference with other growth parameters
4. Presence or absence of dysmorphic features
5. Presence or absence of congenital abnormalities involving other organ systems
6. Careful examination of the skin
7. Careful neurologic and developmental assessment

Accurate measurement and plotting on appropriate charts are critical (see earlier discussion). Head circumference of premature infants is adjusted for the degree of prematurity until about 2 years of age. For infants with birth weight of less than 1,000 g, corrected age is often used until 3 years or when growth has caught up based on normal growth curves. Inspection and palpation of the skull may reveal an asymmetrical skull and face and bony ridging that are suggestive of craniosynostosis, the presence of which leads the pediatrician to a different approach in evaluation and management. A head circumference that is disproportionately small in relation to the child's weight and height is a likely indicator of a CNS condition. When microcephaly is part of generalized growth retardation, or when it is associated with dysmorphic facial features and multiple-organ system involvement, the search for conditions that may have a more systemic effect on the child should be investigated, such as chromosomal disorders, intrauterine infections, or exposure to toxins. Children with congenital microcephaly seem to have a higher frequency of major malformations when compared with normocephalic infants. Examination of the skin may reveal the rash of an intrauterine infection. A thorough neurologic examination should assess for asymmetries, abnormalities in muscle tone, posture, strength, and reflexes. A developmental assessment may reveal generalized psychomotor retardation and motor delays, as well as speech/language and cognitive impairments.

### Laboratory Testing

The laboratory evaluation should be guided by the differential diagnoses. Children who are thought to have intrauterine infections must be tested for prenatal infections (toxoplasmosis, rubella, cytomegalovirus, syphilis, human immunodeficiency virus, herpes) and have ophthalmologic and audiologic evaluations. A microcephalic newborn with other congenital anomalies and atypical facial features should have a genetic consultation and evaluation. Genetic testing is available for many disorders, including chromosomal disorders, Miller-Dieker syndrome, and Rett syndrome. For children with microcephaly and dysmorphic features, the availability of array comparative genomic hybridization (aCGH) testing has enhanced the likelihood of a genetic diagnosis. Metabolic testing is usually not recommended in the evaluation of an asymptomatic newborn with microcephaly; however, it should be considered in cases of postnatal-onset microcephaly, especially with a history of parental consanguinity, episodic symptoms, or developmental delays or regression.

### Imaging

In the evaluation of a child with microcephaly, several neuroimaging modalities are available to identify

abnormalities in brain structure. The yield is significantly higher in cases of severe microcephaly (>3 standard deviations below the mean) compared with mild microcephaly (2–3 standard deviations below the mean). Magnetic resonance imaging (MRI) is most suitable for identifying gray and white matter disease and migration defects such as lissencephaly, pachygyria, and polymicrogyria. However, MRI is limited in its ability to study bone and calcifications. Computed tomography is useful to identify intracranial calcifications that may result from intrauterine infections, the skull abnormalities seen with premature fusion of cranial sutures, and ventricular system abnormalities. In infants with open fontanelles, ultrasonography of the head can be helpful in delineating cranial abnormalities. A skull radiograph can demonstrate intracranial calcifications and the characteristic bone findings in craniosynostosis but cannot detect abnormalities in brain structure. Consultation with a neuroradiologist may be helpful in determining which procedure, if any, is appropriate for a given child.

Practice parameters for the evaluation of the child with microcephaly have been developed by the Quality Standards Subcommittee of the American Academy of Neurology and the Practice Committee of the Child Neurology Society.

## MANAGEMENT

The management of microcephaly is largely symptomatic and preventive. Appropriate prenatal care, maternal education and nutrition, avoidance of teratogenic substances, screening for intrauterine infections, and management of maternal health conditions may minimize the number of preventable cases of microcephaly. Because many children with microcephaly may have other medical issues (eg, cerebral palsy, seizures, ophthalmologic disorders), the pediatrician should monitor for these conditions and initiate the provision of interventions as needed. Children with microcephaly require close follow-up for developmental issues and can benefit from early intervention and special education services as needed. Genetic counseling must be offered to parents who have offspring with genetic disorders. Children suspected to have craniosynostosis require neurosurgical consultation.

### WHEN TO REFER

- Consider for head circumference of more than 2 standard deviations below the mean (especially >3 standard deviations)
- Head circumference deceleration or poor head growth
- Dysmorphic features
- Abnormal neurologic examination and development
- Regression in motor, language, and social skills
- Seizures
- Suspected craniosynostosis

### WHEN TO ADMIT

- Signs of increased intracranial pressure
- Mental status change

## Chapter 179

# NONCONVULSIVE PERIODIC DISORDERS

Sarah M. Roddy, MD

A variety of paroxysmal nonepileptic disorders occur in children. These disorders have a wide range of clinical features that mimic seizures, and distinguishing them from seizures is important so that the child is not treated inappropriately with anticonvulsants. A thorough history is often all that is needed to make the diagnosis, although a few patients may require a more extensive evaluation.

## BREATH-HOLDING SPELLS

Breath-holding spells, or infantile syncope, occur in approximately 5% of children. Most children who have breath-holding spells begin having episodes between 6 and 18 months of age, although spells may begin in the first few weeks of life. The frequency of episodes ranges from once a year to several times daily. The history of the episode and the surrounding events is the most important part of the evaluation of a child who has such spells. Because the familial incidence of breath-holding spells is high, the parents should be questioned about episodes in other family members.

Two types of breath-holding spells occur: cyanotic and pallid. The cyanotic type is more common than the pallid form and is usually precipitated by frustration or anger. During such spells, children cry vigorously and then hold their breath in expiration. Apnea

is followed by cyanosis, with opisthotonic posturing and loss of consciousness. Recovery is usually quick, with return of respiration and consciousness within 1 minute. Evaluation of children who have severe cyanotic breath-holding spells has shown an underlying autonomic system dysregulation that may contribute to the pathophysiologic features of the episodes. Pallid breath-holding episodes are usually provoked by sudden fright or minor injuries, especially falling and hitting the occiput. The child gasps or cries briefly and then abruptly becomes quiet, loses consciousness, has pallor, and becomes limp. The child may then develop clonic jerks. Pallid breath-holding spells are a vasovagal phenomenon. The precipitating event induces a vagally mediated asystole, leading to cerebral ischemia. Ocular compression during simultaneous electroencephalographic and electrocardiographic tracing in children who have pallid breath-holding spells has shown asystole with flattening of the electroencephalogram without electrical seizure activity. The clonic jerks are caused by cerebral hypoxia rather than by epileptiform discharges from the brain.

The prognosis for children who have either type of breath-holding is excellent; most outgrow the episodes by school age. Children who have pallid breath-holding spells may later develop syncope. Treatment is directed mainly at reassuring the family of the benign nature of the episodes. The pediatrician or other physician should emphasize that the episodes are not seizures and that they do not lead to intellectual disability or epilepsy. Because cyanotic episodes are often precipitated by temper tantrums, anger, and frustration, advice about behavior management may be helpful. Anemia has been described as a contributing factor in breath-holding spells, and treating it may reduce the incidence of the episodes. Atropine is effective for pallid breath-holding episodes, but its use is rarely warranted. Anticonvulsants should not be used because they are not effective in treating either type of breath-holding spell (see Chapter 201, Temper Tantrums and Breath-holding Spells).

## SYNCOPE

Syncope, or fainting, is an acute and transient loss of consciousness caused by reduced cerebral perfusion. Episodes are relatively common, particularly among teenagers. Postural hypotension, which may occur after a sudden change from a sitting or reclining position to a standing position, can precipitate an episode. Emotional upset, fright, and overheating are also common provoking stimuli. Cardiac disorders, including arrhythmias, aortic stenosis, and severe cyanotic heart disease, may cause syncope by reducing cardiac output and causing cerebral hypoxia. In rare cases, episodes of syncope have been reported with swallowing, coughing, urinating, and defecating.

Patients have presyncopal symptoms that may include light-headedness, anxiety, sweating, nausea, generalized numbness, and visual changes described as constriction or darkening of vision. Observers notice marked pallor and clammy skin. These symptoms are followed by loss of consciousness and slumping to the floor. Once the patient is recumbent and cerebral perfusion is restored, consciousness returns within a

few seconds. If the patient is held with the head above the body and cerebral perfusion is not restored, clonic movements may occur. As with pallid breath-holding spells, these movements occur as a result of cerebral ischemia rather than epileptiform discharges from the brain. Patients are not disoriented or confused after an episode of syncope, although they may be tired.

The history is important in diagnosing syncope and should include a description of the event by the patient and an observer. Although laboratory evaluation is seldom needed, if atypical elements are involved, such as absence of a precipitating factor or confusion after the episode, an electroencephalogram or a cardiac evaluation, including Holter monitoring, may be appropriate. Evaluation with tilt-table testing can be helpful for children who have unexplained syncope. Treatment consists of teaching the patient and family about managing an episode. Because patients have presyncopal symptoms, they should be instructed to sit or lie down as soon as the symptoms begin, thereby preventing progression to loss of consciousness. If the patient loses consciousness, the parent should place the child in a recumbent position with the head lower than the trunk. Parents often pick up a child who has fainted; they should be cautioned against this action because they may prolong the period of unconsciousness (see Chapter 200, Syncope, for a more detailed discussion of syncope and its causes).

## BENIGN PAROXYSMAL VERTIGO

Benign paroxysmal vertigo of childhood is a disorder characterized by brief attacks of vertigo. Symptoms usually appear within the first 3 or 4 years of life, although they may begin later. Episodes are characterized by abrupt onset, with the child appearing fearful and unable to maintain normal posture and gait. The child may seek support and clutch the parent or abruptly sit down or fall. In severe cases, the child may be limp and incapable of using the extremities. Pallor and diaphoresis are usually apparent, and vomiting and nystagmus sometimes occur. An episode typically lasts less than 30 seconds or, in rare cases, a few minutes. A brief period of postural instability may follow the episode; but within a few minutes, the instability resolves. Consciousness is not altered during the episode, and only rarely does the child feel sleepy after it. The frequency of episodes varies from as many as several weekly to 1 episode every few months. Audiograms are normal. Oculovestibular testing with cold-water calorics is difficult to perform in young children, and results vary. When properly done, testing shows no abnormalities in vestibular function. The results of radiographic studies of the temporal bone and electroencephalographic recordings are also normal. Included in the differential diagnosis of vertigo in childhood are brainstem lesions, posterior fossa tumors, and epilepsy. The history and physical examination usually differentiate benign paroxysmal vertigo from these more serious disorders. In most cases, no treatment is necessary, and anticonvulsants are not effective. Antihistamines such as dimenhydrinate have been used in some patients who have frequent episodes, with an apparent reduction in the number of episodes. Because the frequency of attacks varies,

assessing the effect of therapy accurately is difficult. Attacks of vertigo usually stop spontaneously over a period of a few years. Some children with benign paroxysmal vertigo later develop migraine headaches (see Chapter 140, Dizziness and Vertigo).

### SHUDDERING ATTACKS

Shuddering or shivering episodes are a benign movement disorder that probably occurs in many children at one time or another. The episodes are brief and characterized by paroxysmal rapid tremors involving primarily the head and arms. Some episodes may involve flexion of the head, elbow, trunk, and knees, with adduction of the elbows and knees. Consciousness is not altered during the episodes. The frequency varies, with some children having more than 100 episodes daily. Emotional factors, including excitement, fear, anger, and frustration, may precipitate episodes. Shuddering episodes may start as early as a few months of age or not until later in childhood. The number of episodes usually declines gradually. The pathophysiologic mechanism of the episodes is unclear, although the attacks have been postulated to be an expression of an essential tremor. Electroencephalographic monitoring has shown that the episodes are not epileptiform in nature. In most cases, no treatment is necessary. If episodes are severe and interfere with activities, treatment with propranolol may be helpful. Anticonvulsants are ineffective and should not be used.

### BENIGN NEONATAL SLEEP MYOCLONUS

Sudden brief jerks of the extremities are normal in children and adults when falling asleep. Sleep-related myoclonus in neonates is called *benign neonatal sleep myoclonus*. The myoclonic jerks begin in the first month of life, often within the first day, and are present only during sleep, disappearing when the infant awakens. The jerking movements may start in one extremity and then progress to involve the other extremities, or they may begin bilaterally. The upper extremities are involved more often than the lower extremities. Jerks occur every 2 to 3 seconds for several minutes, although they have been reported to last up to 12 hours. Rocking the crib and repetitive sounds may provoke the myoclonus. Development is normal, and no neurologic deficits are present. Electroencephalographic results are normal, with no epileptiform discharges associated with the myoclonus. The major differential diagnosis of neonatal sleep myoclonus is a seizure disorder. A history of episodes only during sleep and a normal electroencephalogram help differentiate this benign disorder from seizures. The myoclonus usually diminishes gradually during the first 6 months of life, although it has rarely lasted until 3 years. No treatment is necessary. The infants do not subsequently develop epilepsy or cognitive delay.

### NIGHT TERRORS

Night terrors or sleep terrors are a sleep disorder with some features that mimic partial complex seizures. They occur in up to 6% of children, with a peak incidence in late preschool-aged and early school-aged children. Affected children often have a family history

of either night terrors or another sleep disorder. The episodes usually occur during the first 2 hours after falling asleep. The child sits up in bed abruptly and screams or talks unintelligibly. If the child's eyes are open, they have a glazed look. During the episode, the child appears to be hallucinating and does not respond to the parents. Tachycardia and diaphoresis result from activation of the sympathetic nervous system. In some cases, the child may sleepwalk. Night terrors usually last approximately 10 minutes, with the child then relaxing and abruptly falling back to sleep. On awakening, the child does not remember the episode. Night terrors are caused by a rapid partial arousal from deep, slow-wave sleep. Febrile illness and sleep deprivation may trigger night terrors.

Electroencephalography does not show seizure activity during the episodes. It is important to differentiate night terrors from nightmares, which occur later in the sleep cycle, during rapid eye movement (REM) sleep, and are associated with easy arousal and recall of the content, or at least the occurrence, of the nightmare. Night terrors usually occur less often as the child gets older, although episodes may continue into adolescence and adulthood. The nature of the episodes should be explained to the parents. Although parents tend to try to wake and reassure the child, they should be told that the child is not aware of their presence, and attempts to awaken the child are not helpful and may increase agitation. If the child is sleep deprived, parents should take steps to increase the amount of sleep the child is getting. If night terrors persist despite adequate sleep, a sleep study may be needed to evaluate for obstructive sleep apnea, which can trigger night terrors. In most cases, no medication is indicated. However, if episodes are frequent or severe, a benzodiazepine, imipramine, or L-5-hydroxytryptophan may be helpful.

### NARCOLEPSY

Narcolepsy is a sleep-wake disorder characterized by excessive and inappropriate periods of sleep during the day. The daytime sleepiness interrupts activities and does not diminish in response to adequate amounts of sleep at night. Naps may last from a few minutes to longer than an hour. In addition to the excessive daytime sleep, patients often have cataplexy, sleep paralysis, and hypnagogic hallucinations. Cataplexy is a transient partial or complete loss of tone, often triggered by an emotional reaction such as laughter or fright. The individual does not lose consciousness. Sleep paralysis occurs as the patient falls asleep or awakens and is characterized by the inability to move or speak. Hypnagogic hallucinations occur while falling asleep, can be auditory or visual, and may be very frightening to a child.

The estimated prevalence of narcolepsy is 0.02% to 0.05%. Onset usually occurs in the second decade, although it has been reported in toddlers. Sleep studies in patients who have narcolepsy show extremely short sleep onset latency. In narcolepsy, REM sleep occurs within 15 minutes of sleep onset; in healthy patients, 90 minutes of non-REM sleep precede the first REM period. A strong association exists between narcolepsy and the human leukocyte class II

antigen DQB1\*0602. Human leukocyte antigen typing may be helpful but is not diagnostic. The hypocretin peptides that are important for maintaining wakefulness may be absent on cerebrospinal fluid studies, especially in cases involving cataplexy. Sleep studies are important in diagnosing narcolepsy. Included in the differential diagnosis of excessive daytime sleepiness are chronic illness, sleep apnea, hypothyroidism, depression, and seizures.

Narcolepsy is a lifelong condition, but central nervous system stimulants such as methylphenidate and modafinil help reduce the frequency of naps. Tricyclic medications such as imipramine are used to treat cataplexy and the other associated symptoms.

### WHEN TO REFER

- Diagnosis cannot be made by history and physical examination
- Need exists for subspecialty expertise

### WHEN TO ADMIT

- Child needs video electroencephalographic monitoring to evaluate an episode

## Chapter 180

# ODOR (UNUSUAL URINE AND BODY)

Erik Langenau, DO, MS

Unusual odors in children may be a chief complaint, symptom, or sign. The odors may emanate from the breath, urine, skin, sputum, vomitus, stool, or vagina, and they can provide helpful clues in the diagnosis of many specific conditions.

### DEFINITION OF TERMS

Although unusual odors can be caused by many different conditions, bromhidrosis and halitosis require careful attention.

Bromhidrosis, a condition in which sweat is malodorous and offensive, is caused by decomposition of products from the apocrine, eccrine, and sebaceous glands. Apocrine bromhidrosis, which begins after

puberty with a characteristic acrid or sweaty odor, results from a combination of short-chain fatty acids, ammonia, androgenic steroids, hexanoic acid, and saturated ketones and indoles. Eccrine bromhidrosis results from bacterial interaction with moist keratin and is caused by hyperhidrosis, obesity, intertrigo, and diabetes mellitus; it is aggravated by hot weather and occurs primarily in the soles, palms, and intertriginous areas.

Halitosis is an offensive odor emanating from the mouth or air-filled cavities such as the nose, sinuses, or pharynx; it may be physiologic or pathologic, with numerous causes, such as xerostomia (dry mouth), periodontitis, sinusitis, tonsillitis, or gastroesophageal reflux.

### EVALUATION OF UNUSUAL ODORS

The differential diagnosis of unusual odors is extensive and includes numerous systemic, metabolic, toxic, and infectious diseases. The physician may inquire about the presence or absence of an odor when evaluating a child with a particular infection, dermatologic condition, metabolic disease, or ingestion. After a thorough history and physical examination is conducted, the differential diagnosis of an unusual odor can become more focused.

### Chief Complaint

If an unusual body odor is the chief complaint, a thorough history of the present illness helps narrow the differential diagnosis. Relevant questions may include the following:

- When did you first notice the odor?
- What does it smell like?
- Does it smell like anything familiar?
- What is the quality?
- What is the intensity?
- Does it seem to come from a certain part of the body?
- Does bathing or cleaning make it better?
- Are there any other associated symptoms, such as vomiting, weight loss, lethargy?
- Do other members of the family have similar odors?
- Do any family members have metabolic or infectious diseases?
- Have you seen any insertion of a foreign body in the nose, ear, anus, or vagina?
- Has your child taken any oral or topical medications, vitamins, herbal supplements, or toxins?
- How has the odor affected the child and family?

### Physical Examination

In assessing an odor, the examiner should note the character of the odor, determine the patient's age (and stage of pubertal development), check for any other signs or symptoms during a complete examination with the child unclothed, and attempt to localize the odor to a particular body site.

In a routine medical encounter, an odor may be the first observation when the patient enters the examining room. Odors are often difficult to describe because of insufficient standards for classifying, qualifying, quantifying, and teaching about them. Historically and practically, odors have been compared with others

for which physicians have common experience, and odor strength is characterized by such adjectives as strong or faint. In addition, individuals differ in their ability to detect at least some odors and in their assessments of whether certain odors are offensive. Gas-liquid chromatography and enhanced odor classification systems now allow more precise identification of odors. Artificial nose technology, which can sense a wide range of volatile chemicals and be trained in pattern recognition, may soon become a tool to supplement the physician's own nose. Artificial noses or bioelectronic noses have already been used to detect diseases such as tuberculosis, urinary tract infections, *Helicobacter pylori* infection, gastroesophageal reflux disease, bacterial vaginosis, diabetes, and a number of cancers.

If a patient reports an intermittent unusual odor that is never detected by others, then the possibility of temporal lobe epilepsy with olfactory manifestations should be entertained. On the other hand, if the physician notices a clearly offensive body odor, but the patient or parent does not, then anosmia should be considered. Causes of impaired olfaction may include various endocrinopathies such as Kallmann syndrome, diabetes, Turner syndrome, and hypothyroidism; neuropsychiatric conditions such as schizophrenia; infections such as rhinitis and sinusitis; autoimmune diseases such as Sjögren syndrome, granulomatosis with polyangiitis (formerly known as Wegener granulomatosis) and multiple sclerosis; or medications including metronidazole, tetracycline, captopril, and amphetamines.

Physicians should also be aware that odor recognition involves complicated molecular and genetic mechanisms. Sex, age, and genetic variation may lead to differences in abilities and thresholds for detecting odors. Physicians and patients may therefore vary in their ability to detect certain odors.

## DIFFERENTIAL DIAGNOSIS OF UNUSUAL ODORS

An array of odors can be associated with the human body and clothing, and subtle differences in odor can be found among people as well. Therefore the first task may be to decide whether a particular odor truly is peculiar and whether it emanates from the body. The odor may be simply a normal body odor that draws attention because of its intensity or because the complainant is unusually sensitive to or concerned about it.

### Normal Body Odor

Normal body odors derive from secretions of the sweat and apocrine glands, vagina, cervix, respiratory tract, urine, feces, breath, and flatus. Odor may be produced or modified by the action of normal or abnormal microbial flora.

In Western culture, people often minimize body odors by frequently changing their clothing, bathing, and using deodorants, antiperspirants, mouthwashes, douches, or scents applied to the skin. If one of these artificial odors is too strong, then the physician may wonder what the patient is trying to hide. On the other

hand, if a patient does not practice these customs, then the physician may detect an odor that is offensive and then must decide why the patient is not complying with social expectations.

Body odor changes with puberty, and a characteristic adult odor may prompt a child (or the child's parents) to seek medical attention.

### Axillary Odor

Axillary odor, which varies in intensity from person to person, is often the strongest odor associated with adolescents and adults. Its pungency has long been attributed to the action of aerobic diphtheroids on apocrine secretions. Recent work has identified odor-binding proteins that originate in the apocrine glands. The most abundant of the smelly compounds may be (E)-3-methyl-2-hexenoic acid. Bacterial decomposition of androsterone is another possible cause of axillary odor. Axillary hair seems to retain or spread odor.

Some adolescents and adults have axillary odor that is unusually strong, a condition called osmidrosis axillae or axillary apocrine bromhidrosis. The odor emanates from the apocrine glands. Possible explanations include specific features of apocrine androgen metabolism, bacterial alteration of sweat, and abnormally large and numerous apocrine glands. A variety of topical interventions, as well as surgical excisions, have been used to treat this condition.

### Vaginal Odor

The odor of postpubertal vaginal secretions varies among individuals and with the menstrual cycle. Vulvar secretions, vaginal wall transudates, exfoliated cells, cervical mucus, fluids from the endometrium and uterine tubes, and metabolic products of the vaginal microflora all contribute. Some people characterize the resulting odor as unpleasant, even in the absence of vaginitis. Odor during menses is usually rated as the most offensive. Some individuals may be concerned about these normal odors. The rotten fish smell of the vaginal discharge associated with bacterial vaginosis is caused by trimethylamine.

### Mouth Odor

The odor of a healthy mouth is assumed to be inoffensive in childhood; however, *bad breath* is not uncommon, even in an otherwise well child. Halitosis in the absence of disease is thought to be caused by volatile sulfur compounds (hydrogen sulfide and methyl mercaptan), which are formed when the oral flora metabolize proteins that are found in the saliva or adhering to the teeth, tongue, or gums. Halitosis is exacerbated by infrequent eating and drinking, which ordinarily have a flushing action. Acutely, halitosis may accompany a variety of childhood respiratory tract and gastrointestinal infections. Persistent halitosis should prompt evaluation for dental or gingival disease, a nasal foreign body, lung disease, or gastroesophageal reflux.

Simple oral hygiene can temporarily modify mouth odor. Brushing the teeth and the dorsoposterior surface of the tongue and then rinsing with water or a mouthwash may well reduce both the concentrations of volatile sulfur compounds and the offensive odor.

### Foot Odor

Eccrine bromhidrosis, tinea pedis (athlete's foot), and pitted keratolysis have been associated with increased foot odor. Each of these conditions may be exacerbated by occlusive footwear (eg, boots) and a hot, humid climate. The odor from eccrine bromhidrosis of the feet is thought to result from the breakdown of keratin and lipids by diphtheroids; fatty acid metabolites may be the agents responsible for the odor. Pitted keratolysis (plantar keratolysis puncta) is characterized by white plaques and shallow pits on the plantar surface. Various gram-positive bacteria and dermatophytes have been identified in affected patients. The odor is thought to be related to the breakdown products (such as thiols and thioesters) of these microorganisms within the stratum corneum. Conditions associated with foot odor may respond to a combination of moisture control, topical antibiotics, and antifungal agents.

### Metabolic Abnormalities

Certain metabolic defects are associated with an unusual odor of the urine, sweat, and other body fluids because of accumulation of odoriferous metabolic precursors or byproducts. These metabolic disorders and associated odors are listed in Table 180-1. Metabolic disorders should be suspected if an infant has an unusual body odor, especially if the patient is ill appearing, malnourished, or ketotic. Recognizing the odor in a compatible clinical situation may lead to early diagnosis, and prompt treatment may prevent progressive brain damage or death. A specialist in metabolic diseases should be consulted, and an appropriate diet should be started while a more

thorough metabolic evaluation is being completed. The odor itself may lead to embarrassment, low self-esteem, and psychosocial problems. In some conditions, dietary manipulation may reduce the malodor as well as other symptoms.

### Foreign Bodies

Retention of a foreign body in an orifice may lead to a focal foul smell. Retained foreign bodies within the vagina (eg, tampons, diaphragms), auditory canals, and nostrils are common causes of local foul odor. A retained foreign body may also be related to a generalized body odor because odoriferous substances are absorbed and secreted in sweat. Nasal foreign bodies are the most commonly associated with this condition.

### Inhalation, Poisoning, and Ingestion

When inhalation or ingestion of a toxic substance is suspected, odor may provide a clue to the substance involved. Common associations are listed in Table 180-2. When puzzled, the physician should consult a poison control center.

Penicillin and cephalosporins give the urine a medicinal or musty smell. Topical benzoyl peroxide has been implicated in at least 1 case of persistent body odor. Thiourea compounds give the breath a sweet smell, resembling that of decaying vegetables. Newborns have smelled spicy when their mothers ate particular curries before labor.

### Other Diseases

Odor may suggest either the presence of an infection (Table 180-3) or other acquired medical conditions (Table 180-4).

**Table 180-1** Metabolic Abnormalities Associated With Unusual Odor

DISEASE	DESCRIPTION OF ODOR	CLINICAL FEATURES	METABOLIC DEFECT
3-hydroxy-3-methylglutaryl-CoA lyase deficiency	Cat urine	Malaise, hypoglycemia, hepatomegaly, transaminitis, mild acidosis	3-hydroxy-3-methylglutaryl-CoA lyase
Glutaric aciduria type II (multiple acyl-CoA dehydrogenase deficiency)	Sweaty feet, acrid, stale	Hypoglycemia, hypotonia, hepatomegaly, respiratory distress, death	Electron transfer flavoprotein (ETF) or ETF:ubiquinone oxidoreductase (ETF:QO)
Hawkinsinuria	Swimming pool	Failure to thrive, hepatomegaly, anemia, irritability	4-hydroxyphenylpyruvate dioxygenase
Hypermethioninemia	Boiled cabbage	Usually asymptomatic. Some develop intellectual disability, dystonia.	Methionine adenosyltransferase
Isovaleric acidemia	Sweaty feet, acrid	Acidosis, vomiting, dehydration, coma, mild-to-moderate intellectual disability, aversion to protein foods	Isovaleric acid CoA dehydrogenase
Ketoacidosis	Fruity, acetone-like, decomposing apples	Vomiting, dehydration, altered mental status, lethargy	Ketoacidosis (eg, from starvation or insulin deficiency)
Maple syrup urine disease	Maple syrup, burnt sugar, curry, malt, caramel, fenugreek beans	Severe form: feeding difficulty, vomiting, lethargy, acidosis, seizures, coma leading to death in first months of life	Mitochondrial branched-chain alpha-keto dehydrogenase complex

**Table 180-1** Metabolic Abnormalities Associated With Unusual Odor—cont'd

DISEASE	DESCRIPTION OF ODOR	CLINICAL FEATURES	METABOLIC DEFECT
		Intermediate form: mild acidosis, intellectual disability, developmental delay, ophthalmoplegia Intermittent form: episodic ataxia and lethargy that may progress to coma Thiamine-responsive form: respond to supplementation E3-deficient form: variable expression	
Multiple carboxylase deficiency	Tomcat urine	Failure to thrive, hypotonia, vomiting, seizures, rash	Holocarboxylase synthetase
Oasthouse urine disease (methionine malabsorption syndrome; Smith-Strang disease)	Dried celery, malt, hops, yeast, beer	Diarrhea, intellectual disability, spasticity, attacks of hyperpnea, fever, edema	Kidney and intestinal transport of methionine, branched-chain amino acids, tyrosine, and phenylalanine
Phenylketonuria	Musty; similar to a mouse, horse, wolf, or barn	Vomiting, progressive mental retardation, microcephaly, eczema, decreasing pigmentation, seizures, spasticity	Phenylalanine hydroxylase
Trimethylaminuria (fish odor syndrome)	Dead or rotting fish	Usually asymptomatic with isolated finding. Fish odor of urine and body.	Trimethylamine oxidase
Tyrosinemia	Boiled cabbage, rancid butter	Liver failure, death	Fumarylacetoacetate hydrolase deficiency

Data derived from multiple sources.

**Table 180-2** Inhalations, Poisonings, and Ingestions Associated With Recognizable Odors

ODOR	SITE	SUBSTANCE IMPLICATED
Bitter almond	Breath	Cyanide (chokecherry, apricot pits), jetberry bush
Burned rope	Breath	Marijuana
Camphor	Breath	Naphthalene (mothballs)
Carrots	Breath	Water hemlock (cicutoxin)
Coal gas	Breath	Coal gas (associated with odorless but toxic carbon monoxide)
Disinfectant	Breath	Phenol, creosote
Fishy	Breath	Zinc or aluminum phosphide
Fruity, acetone or decomposing apples	Breath	Lacquer, salicylates, chloroform
Fruity, alcohol	Breath	Alcohol (ethanol, isopropyl alcohol), phenol, acetone, amyl nitrites ( <i>poppers</i> )
Fruity, pearlike	Breath	Chloral hydrate, paraldehyde
Garlic	Breath, vomitus, stool	Arsenic
Glue	Breath, vomitus	Phosphorus, tellurium, parathion, malathion, dimethyl sulfoxide, selenium
Hydrocarbon	Breath, vomitus	Toluene, solvents ( <i>huffing</i> )
Medicinal, musty	Urine	Hydrocarbons
Metallic	Breath	Penicillins, cephalosporins
	Stool	Iodine
	Vomitus	Arsenic
Rotten eggs	Breath	Arsenic, phosphorus
Severe bad breath	Breath	Hydrogen sulfide mercaptans, disulfiram, dimethyl sulfate, N-acetylcysteine
Shoe polish	Breath	Amphetamines
Stale tobacco	Breath	Nitrobenzene
Sulfides or amines	Skin	Nicotine
Violets	Urine, vomitus	War gases
Wintergreen	Breath	Turpentine
		Methyl salicylate

Data derived from multiple sources.

**Table 180-3**      **Odor as a Clue to Infection**

INFECTION	ODOR
<b><i>Respiratory and Ear, Nose, and Throat Infections</i></b>	
Candidiasis	Sweet, fruity
Diphtheria	Sweet
Intranasal foreign body	Foul and putrid
Lung abscess, empyema, bronchiectasis, fetid bronchitis	Foul, putrid breath or sputum
<i>Pseudomonas</i> infection, otitis externa	Foul cerumen
Rubella	Fresh-plucked feathers
Trench mouth, tonsillitis, gingivitis	Severe halitosis
Tuberculous lymphadenitis (scrofula)	Stale beer
Typhoid fever	Fresh-baked brown bread
Yellow fever	Butcher shop
<b><i>Skin Infections</i></b>	
<i>Candida</i> (skin)	Heavily sweet
Decubitus ulcer	Foul
Diphtheria (skin)	Sweet
Erythroderma	Rancid
Hidradenitis suppurativa	Lingering, pungent
Pitted keratolysis (gram-positive bacteria and dermatophytes)	Cheesy, sweaty, rotten smell from feet
<i>Pseudomonas</i> skin infection (burns)	Musty, fruity, grapelike, wet corn tortillas
Syphilis (condyloma latum)	Foul
Tinea capitis	Mousy, mouse urine–like
<b><i>Genitourinary Infections</i></b>	
Bacterial vaginosis	Amine, fishy vaginal discharge
Genital warts (condyloma acuminatum)	Foul
Urinary tract infection with urea-splitting bacteria	Ammoniacal urine
Vaginal foreign body, vaginitis	Foul vaginal discharge
<b><i>Gastrointestinal Infections</i></b>	
Rotavirus gastroenteritis	Full
Shigellosis	Rancid stool
<b><i>Neurologic Infections</i></b>	
<i>Cryptococcus</i> meningitis	Alcohol smell to cerebrospinal fluid
<b><i>Miscellaneous Infections</i></b>	
Chorioamnionitis	Foul-smelling amniotic fluid
<b><i>Infectious Etiologic Agents</i></b>	
Anaerobic bacteria	Foul-smelling wound, rotten apples
<i>Candida</i> infection	Sweet, fruity, beer odor in peritoneal dialysate
<i>Clostridium</i> gas gangrene	Rotten apples
Proteolytic bacteria	Pus that smells similar to feces or overripe cheese
<i>Proteus</i> infection	Mousy
<i>Pseudomonas aeruginosa</i>	Musty, fruity, grapelike, wet corn tortillas

Data derived from multiple sources.

**Table 180-4**      **Other Conditions Associated With Specific Odors**

DISEASE	ODOR
<b><i>Systemic Diseases</i></b>	
Hepatic failure	Breath: musty fish, raw liver, feces, rotten eggs, or newly mown clover ( <i>Fetor hepaticus</i> ) (caused by mercaptans such as dimethyl sulfide)
Ketoacidosis (diabetes or starvation)	Breath: fruity, acetone-like, decomposing apples (caused by ketones)
Uremia	Urine: fishy (caused by dimethylamine and trimethylamine) Breath: ammoniac (caused by ammonia)
<b><i>Vitamin Deficiencies</i></b>	
Pellagra (niacin deficiency)	Sour or musty bread
Scurvy (vitamin C deficiency)	Putrid
<b><i>Dermatologic Conditions</i></b>	
Psoriasis (pustular)	Skin: heavy
Skin diseases with protein breakdown (pemphigus)	Skin: foul, unpleasant

**Table 180-4** Other Conditions Associated With Specific Odors—cont'd

DISEASE	ODOR
<b>Gastrointestinal Conditions</b>	
Malabsorption	Feces: foul
Melena (gastrointestinal bleeding)	Feces: foul
<b>Surgical Conditions</b>	
Esophageal diverticulum	Breath: feculent, foul
<b>Surgical Conditions cont'd</b>	
Intestinal obstruction	Breath: feculent, foul Vomitus: feculent
Nasal foreign body	Skin and nasal cavity: fetid, putrid
Peritonitis	Vomitus: fecal
Portacaval shunt, portal vein thrombosis	Breath: sweet
<b>Miscellaneous</b>	
Acute tubular necrosis	Urine: stale water
Trans-3-methyl-2-hexanoic acid, which may or may not be elevated in patients with schizophrenia	Sweat and skin: unpleasant, pungent, heavy

Data derived from multiple sources.

## SUMMARY

Once an odor is identified and evaluated, a proper diagnostic and treatment plan can begin. Identification of odors can be impeded by poor association between odors and names and failure to retrieve the name of an odor. Physicians can be trained to improve their sense of odor recognition with the aid of educational materials (study guides), simulations with volatile samples on rounds, surgical simulators, and sniffing bar test tubes.

Odor is imprecise. Not surprisingly, with many other diagnostic aids at hand, today's physicians have minimized olfactory cues. However, odor should not be neglected; it may be the patient's primary concern, causing severe psychosocial distress. Odor identification may provide diagnostic clues that may aid in the detection and treatment of an underlying disease process.

## Chapter 181 PETECHIAE AND PURPURA

Lisa Figueiredo, MD; Adam S. Levy, MD

## INTRODUCTION

Petechiae and purpura result from a wide variety of underlying disorders and may occur at any age.

Petechiae are small (1–3 mm), red, nonblanching macular lesions caused by intradermal capillary bleeding (Figure 181-1). Purpura are larger, typically raised lesions resulting from bleeding within the skin (Figures 181-2 and 181-3). Purpura can vary somewhat in color based on the age of the lesion as the blood within the skin is metabolized and fades. Similar to petechiae, purpura do not blanch and may occur anywhere on the body.

## EVALUATION

The evaluation of a patient with petechiae or purpura begins with a complete history that can readily eliminate most disorders from the differential diagnosis. Special attention must be paid to recent trauma, bleeding history, medication use, and symptoms consistent with infection, malignancy, and autoimmune, vasculitic, connective tissue, or rheumatologic disorders. Physical examination should determine whether the skin findings are isolated or evidence that a more generalized process is present. Particular physical findings to evaluate include hepatosplenomegaly, lymphadenopathy, arthritis, arthralgias, or findings that are consistent with an acute viral syndrome. The history and physical examination will dictate the appropriate laboratory evaluations, but at a minimum, a complete blood count with platelets and differential count, as well as assessing prothrombin time and partial thromboplastin time, are typically indicated. Likely diagnoses are detailed here, and the complete evaluation indicated will be discussed.

## DIFFERENTIAL DIAGNOSIS—GENERAL CONSIDERATIONS

Neither petechiae nor purpura are pathognomonic of a specific disorder. The physician must entertain a broad differential diagnosis and consider disorders of hemostasis as well as infection, autoimmune disorders, trauma, malignancy, and other rare causes (eg, vasculitis, connective tissue disorders). The age at

**Figure 181-1** Cutaneous petechiae on the shins and ankles: nonblanching, erythematous macules, often less than 3 mm in size.

**Figure 181-3** Palpable purpura of the lower extremity: erythematous, nonblanching papules that often measure more than 3 mm in size.

**Figure 181-2** Occasional petechiae on the face and large, bullous hemorrhages on the buccal mucosa.

presentation, overall appearance, and the extent of the lesions may help define the underlying pathophysiologic mechanism. For example, scant petechiae on the face of a well-seeming newborn would not be particularly concerning after a vaginal delivery because these lesions are likely caused by the trauma of passing through the birth canal. However, a newborn with diffuse petechiae warrants further evaluation. If the child seems ill, then sepsis must be strongly considered; if

the child seems well, then a platelet disorder should be considered. Thus, petechiae and purpura must be evaluated in the overall context of the patient, severity and extent of the lesions, and history and age of the patient.

With petechiae or purpura, the possibility of a hemostatic defect is always a concern. For isolated petechiae, the physician must consider a primary platelet disorder (ie, low platelet number, platelet dysfunction). Purpura may result from a platelet disorder or other coagulation defect, which can be classified as primary or as a secondary phenomenon from an underlying disease. Platelet disorders can also be classified into disorders of platelet production, disorders of platelet survival (destruction), or disorders of platelet function. In the case of connective tissue disorders, easy bruising is not secondary to a hemostatic defect, but rather is caused by the fragility of the capillaries and the perivascular connective tissues. As such, easy bruising and bleeding may be characteristic manifestations of disorders unrelated to the commonly considered clotting and platelet disorders. In general, however, when presented with a patient with petechiae and purpura, the physician must consider thrombocytopenia as the proximate cause.

The normal platelet count is between 150,000 and 450,000/mm. Patients with a platelet count greater than 80,000 will be hemostatically normal as long as platelet function is not altered. With a platelet count between 50,000 and 80,000, increased bleeding with trauma is likely, but spontaneous bleeding would be unusual. Between 20,000 and 50,000, a mild bleeding diathesis is expected. With a count of less than 20,000, spontaneous mucosal bleeding can occur, and a count of less than 10,000 is concerning for spontaneous severe bleeding.

### Infectious Causes of Petechiae and Purpura

The mechanism by which a variety of viruses cause thrombocytopenia is not clear and may involve decreased platelet production or immune-mediated

destruction. Live virus vaccinations, notably varicella and measles, can cause moderate thrombocytopenia. Cytomegalovirus has been implicated in thrombocytopenia, but treatment of cytomegalovirus has not affected the outcome of patients monitored for chronic thrombocytopenia. Parvovirus has been associated both with isolated thrombocytopenia and with pancytopenia. Dengue fever and other viral hemorrhagic fevers are known to cause thrombocytopenia, and patients may develop petechiae and purpura as a result. Rickettsial diseases such as Rocky Mountain spotted fever may produce a petechial rash. Alterations of the endothelial lining of blood vessels cause thrombi formation and platelet destruction. Thrombocytopenia and disseminated intravascular coagulation (DIC) may develop. Malaria can also cause either mild or profound thrombocytopenia through mechanisms that are not well defined. HIV has been associated with thrombocytopenia resulting from bone marrow suppression (ie, poor production) and immune-mediated destruction.

Platelet consumption is common in children with bacteremia and sepsis even before frank DIC has developed. In an ill-appearing child with petechiae or purpura, infectious causes must be considered and appropriate antibiotics administered based on likely pathogens. Bacterial meningitis in particular must be considered for the febrile ill child with petechiae or purpura.

Purpura fulminans has been associated with viral infections, as well as *Streptococcus* and *Meningococcus* species. Microscopic thromboses in arterioles result in purpura and infarction and bleeding within the skin and subcutaneous tissue. These lesions may coalesce and become necrotic, and patients typically develop full DIC.

### Disorders of Platelet Production: Malignancy and Bone Marrow Failure Syndrome

Although most patients with petechiae or purpura have a benign process, perhaps the greatest concern for the physician and parents is malignancy. As such the history must rule out the classic signs and symptoms of malignancy, including fevers, night sweats, weight loss, lymphadenopathy or other masses, pallor, malaise, bone pain, and anorexia. Of course, many of these symptoms overlap with those seen in infectious and autoimmune processes; thus the physical examination will help the physician greatly. Petechiae or purpura in the setting of hepatosplenomegaly or impressive lymphadenopathy would put leukemia high on the differential diagnosis. Other marrow-infiltrating malignancies must also be considered. If the history or physical examination is consistent with a malignancy, then in addition to a complete blood count and screening coagulation studies, a comprehensive metabolic panel, liver function tests, lactate dehydrogenase, and uric acid should be immediately obtained. A manual differential count of the peripheral blood should be performed as well. An important point to note is that the absence of leukemic blasts on a peripheral blood smear does *not* rule out leukemia. The diagnosis of leukemia can be made if peripheral blasts are present; however, having few or no peripheral blasts

seen on routine microscopy is not uncommon for patients with leukemia.

Isolated profound thrombocytopenia is not likely to result from a malignancy; however, when more than 1 cell line on a blood count is abnormal, a bone marrow process must be considered. Laboratory findings consistent with malignancy include elevated lactate dehydrogenase, and an elevated uric acid and abnormal serum electrolytes may result from tumor lysis even before therapy is started. A chest radiograph should be obtained immediately because patients may have occult but massive mediastinal lymphadenopathy.

Petechiae and purpura may be the presenting signs in patients with bone marrow failure secondary to nonmalignant processes. Abnormal hematopoiesis usually causes alteration of more than 1 cell line or all cell lines (pancytopenia). Bone marrow failure may occur secondary to infectious processes (viral, bacterial with sepsis), medication use (notably a variety of antibiotics and anticonvulsants), profound nutritional deficits, or rare bone marrow failure syndromes (eg, Fanconi anemia, myelodysplastic disease, Wiskott-Aldrich syndrome). Bone marrow aspiration and biopsy are usually indicated to rule out malignancy and define the abnormal hematopoiesis.

### Disorders of Platelet Function: Primary Platelet Disorders

Petechiae and purpura may result from a primary platelet disorder, either qualitative or quantitative. The qualitative disorders result from platelet dysfunction; that is, the absolute platelet number is normal, but the platelets lose normal hemostatic function. In most instances, platelet dysfunction is acquired and results from medication use. The classic example is aspirin, which causes the irreversible inhibition of cyclooxygenase within platelets. Other causes of acquired platelet dysfunction include uremia and liver disease, although the mechanisms of poor platelet function in these settings are not clear.

Although von Willebrand disease is not a primary platelet disorder, patients commonly present with painless mucocutaneous bleeding. For this reason it should be considered in patients who have petechiae and purpura with a normal platelet count and no other obvious systemic disease. Von Willebrand disease is the most common bleeding disorder and affects approximately 1% of the population. It results from a qualitative or quantitative deficiency of von Willebrand factor, a protein required for platelet adhesion. Coagulation screening along with factor VIII and von Willebrand factor assays can establish the diagnosis.

A variety of platelet function disorders can be considered in patients with a normal to near-normal platelet number but who are bleeding and have petechiae or purpura. These disorders, which are rare, can be diagnosed by a hematologist with specialized platelet aggregation studies or morphologic study of platelets. Such disorders include Glanzmann thrombasthenia, Hermansky-Pudlak syndrome, and Chédiak-Higashi syndrome. Bernard-Soulier syndrome, an inherited platelet disorder, is characterized by variable thrombocytopenia and large defective platelets.

### Disorders of Platelet Survival (Destruction)

Isolated thrombocytopenia in an otherwise well child may lead to petechiae or purpura as the chief complaint. Idiopathic (or immune) thrombocytopenic purpura is a diagnosis of exclusion that produces profound isolated thrombocytopenia and petechiae or purpura but few other findings on physical examination. The laboratory workup should be normal except for thrombocytopenia. No other blood cell line is affected, and microscopic review of the blood reveals platelets that are too few in number but large in size, indicating that they are young. Idiopathic thrombocytopenic purpura is a disorder in which the platelet lifespan is reduced to minutes or hours rather than the normal several days. The incidence is highest in children between 2 and 8 years of age. Although physicians performed bone marrow aspirates in the past to rule out malignancy or other bone marrow failure syndromes, most now think that the diagnosis can be made clinically, and bone marrow studies are rarely indicated.

Typically, one-third of the total body platelet mass is sequestered within the spleen at any time. Whatever the cause of increased spleen size, mild thrombocytopenia may result. Common causes of hypersplenism include liver disease, a variety of infections (including Epstein-Barr virus and malaria, among others), and metabolic diseases (eg, Gaucher disease). Hypersplenism alone does not typically cause platelet counts below 50,000. Alternative explanations should be considered for patients with moderate-severe thrombocytopenia.

Henoch-Schönlein purpura is an autoimmune vasculitic disorder that often presents with palpable purpura. The classic distribution of purpura is on the buttocks and legs, but purpura may be more disseminated. Laboratory evaluations fail to reveal an identifiable coagulopathy, nor is there a defect in the quality or quantity of their platelets. The etiology of the palpable purpura is thought to be secondary to the vasculitis resulting in inflammation and weakening of the vessel walls. Other findings in Henoch-Schönlein purpura may include arthritis, arthralgias, abdominal pain, and renal impairment.

Hemolytic uremic syndrome (HUS) produces a constellation of findings, including thrombocytopenia, hemolytic anemia, and renal failure, and has been associated with a variety of infections, most notably *Escherichia coli* O157:H7.

Thrombotic thrombocytopenic purpura (TTP) shares some clinical features with HUS but is a distinct syndrome related to either inherited or acquired loss of function in the ADAMTS13 protease that cleaves von Willebrand factor. TTP, rarely seen in children, is characterized by purpura, thrombocytopenia, DIC, hemolytic anemia, thrombotic strokes, and elevated lactate dehydrogenase.

Giant vascular malformations may cause intravascular destruction of platelets. Kasabach-Merritt syndrome is the classic example of a giant hemangioma causing severe thrombocytopenia secondary to platelet destruction. These lesions are generally readily apparent; however, multiple smaller vascular malformations that are more difficult to define may

cause platelet destruction as well. Although laboratory evaluation often fails to reveal a coagulopathy, thrombocytopenia or altered hemostasis may be associated with rare vascular disorders and connective tissue syndromes such as the hereditary telangiectasias, Ehlers-Danlos syndrome, Marfan syndrome, and osteogenesis imperfecta.

### SUMMARY

Petechiae and purpura may result from a variety of mechanisms requiring the physician to obtain a complete history and perform a thorough physical examination. Both primary hematologic disorders and systemic disorders are in the differential diagnosis. Prompt referral to a pediatric hematologist may be indicated to rule out malignancy or help manage altered hemostasis.

#### WHEN TO REFER

- Platelet count less than 100,000/mm<sup>3</sup>
- Diffuse petechiae or purpura
- Focal petechiae or purpura not clearly associated with trauma
- Evidence of more than 1 cell line abnormality on complete blood count

#### WHEN TO ADMIT

- Patient with toxic appearance
- Moderate to severe bleeding
- Concern for poor adherence

## Chapter 182 POLYURIA

Ryan S. Miller, MD; Samuel M. Libber, MD; Leslie Plotnick, MD

Polyuria, or excessive urinary volume, is a symptom common to many pediatric disorders. It may be defined clinically as urine production of more than 2 L/m<sup>2</sup>/24 hours or functionally as inappropriately high urine output relative to circulating volume and osmolality (Table 182-1). Although polyuria is often associated with polydipsia, frequent urination, and nocturia, these features may occur with normal urine output. Differentiating polyuria from other conditions depends on total urine output. In situations in which

**Table 182-1** Normal Urine Volume

AGE RANGE	DAILY OUTPUT (24 hr)
Newborn	150 mL/kg
Infant	110 mL/kg
Older child	40 mL/kg

the exact daily urinary volume is unknown, a detailed history of fluid intake and urinary habits may help delineate the primary symptom.

With an older child, the parent may perceive an increase in fluid intake to be more prominent than polyuria. However, infants with polyuria, because they do not have independent access to fluids, are more likely to fall into negative water balance, with weight loss, dehydration, and electrolyte disturbances. Chronic or recurrent electrolyte disturbances in unrecognized diabetes insipidus (DI) may result in growth failure and central nervous system (CNS) injury.

### **PATHOPHYSIOLOGIC FEATURES**

Normal serum osmolality and water balance are maintained primarily by release of arginine vasopressin (antidiuretic hormone [ADH]), thirst, and kidney function. Serum osmolality is tightly regulated—an increase in osmolality as small as 1% stimulates measurable release of vasopressin from the posterior pituitary. Vasopressin binds the V2 receptor of the renal tubules, resulting in insertion of aquaporin-2 protein at the apical surface of cortical cells and allowing water to enter the cell. Under normal conditions, plasma osmolality is maintained within a narrow range—about 285 to 290 mOsm/kg. Vasopressin levels rise as plasma osmolality increases above this range. However, maximal antidiuresis is reached at a plasma vasopressin concentration of 4 pmol/L, at which point urine cannot be further concentrated (Figure 182-1).

Vasopressin alone cannot restore fluid balance and osmolality; fluid replenishment is also required. Small increases in osmolality have been shown experimentally to stimulate thirst by increasing the concentration of solutes such as sodium chloride and sucrose (solutes that do not readily cross nerve cell membranes). This action results in intracellular dehydration, activating osmoreceptors in the brain that initiate neural mechanisms and resulting in generation of thirst. The osmolality at which thirst is experienced is likely higher than the point at which vasopressin production rises.

### **DIFFERENTIAL DIAGNOSIS**

Polyuria can be caused by any one of several conditions that play a role in water balance, each of which leads to the excretion of large volumes of dilute urine. Disorders of water balance fall into 4 major categories: central DI, nephrogenic DI, excessive fluid intake, and osmotic diuresis. DI is characterized by polyuria, polydipsia, dilute urine, dehydration, and hypernatremia. Central DI results from a deficiency in vasopressin secretion, whereas nephrogenic DI is the result of

**Figure 182-1** Relation between urine osmolality and plasma arginine vasopressin under various states of hydration. The stippled area is the normal reference range. LD represents the limit of detection of the assay (0.3 pmol/L). (From Baylis PH, Cheetham T. *Diabetes insipidus*. Arch Dis Child. 1998;79(1):84–89, with permission.)

reduced renal sensitivity to circulating vasopressin. Polyuria can also be a manifestation of excessive persistent fluid intake (primary polydipsia) or osmotic (solute) diuresis, as in uncontrolled diabetes mellitus (DM). In reaching a diagnosis in a patient who has polyuria, the physician must consider the systems involved in maintaining normal serum osmolality and water balance (Box 182-1).

### **Central Diabetes Insipidus**

Central or neurogenic DI is a condition in which secretion of vasopressin by the posterior lobe of the pituitary gland is inadequate to maintain normal serum osmolality, resulting in diuresis of varying degrees of severity. Of the known causes of central DI, nearly one-half of all cases result from a primary brain tumor, and about 18% are from histiocytosis or infiltrative processes. About 25% of cases are considered idiopathic. Familial vasopressin deficiency, also known as familial neurohypophyseal diabetes insipidus (FNHDI), is typically an autosomal dominant disorder and is rare, accounting for about 5% of all cases of DI. Although many mutations have been reported in the arginine vasopressin (AVP) gene, most cases involve mutations in the gene for neurophysin II (NP<sub>II</sub>), the carrier protein for AVP. In FNHDI, symptoms typically do not appear until 5 to 10 years of age. The syndrome consisting of DI, DM, optic atrophy, and deafness (DIDMOAD syndrome) typically presents in early childhood. Vasopressin deficiency is associated with certain congenital malformations (eg, septo-optic dysplasia, holoprosencephaly) and can result from CNS injury or tumor resection. After head trauma or surgery, patients may have a period of antidiuresis

### BOX 182-1 Differential Diagnosis of Polyuria in Childhood

1. Neurogenic vasopressin deficiency
  - a. Familial
  - b. Idiopathic
  - c. Congenital malformations (septo-optic dysplasia, holoprosencephaly, encephalocele)
  - d. Acquired
    - i. Head trauma
    - ii. Vascular event (thrombosis or hemorrhage)
    - iii. Postinfection (meningitis, encephalitis, congenital cytomegalovirus, toxoplasmosis)
    - iv. Tumor (craniopharyngioma, germinoma, optic glioma)
    - v. Systemic infiltrative diseases (histiocytosis, syphilis, tuberculosis, sarcoidosis)
    - vi. Inflammatory (lymphocytic hypophysitis)
    - vii. Guillain-Barré syndrome
    - viii. Autoimmune disorders
2. Renal vasopressin insensitivity
  - a. Familial nephrogenic diabetes insipidus
    - i. V2 receptor gene defect (X-linked)
    - ii. Aquaporin-2 gene defect (autosomal recessive)
  - b. Acquired
    - i. Postobstructive
    - ii. Drug-induced (lithium, amphotericin B)
    - iii. Associated with systemic disease (sickle cell disease, sarcoidosis, amyloidosis)
    - iv. Metabolic (hypercalcemia, hypokalemia)
3. Other renal disorders
  - a. Renal tubular defects (cystinosis, distal renal tubular acidosis, Bartter syndrome, renal Fanconi syndrome, ARC syndrome)
  - b. Nephronophthisis
4. Excessive fluid intake
  - a. Primary polydipsia
  - b. Water intoxication
5. Osmotic diuresis
  - a. Diet-induced
  - b. Drug-induced
  - c. Diabetes mellitus (type 1 or 2)

ARC, arthrogryposis, renal tubular dysfunction, and cholestasis.

after transient polyuria, followed by persistent central DI (triple-phase response).

In recent years, fewer cases of DI have been diagnosed as idiopathic, and a higher proportion have been diagnosed as occurring secondary to CNS infection or intracranial birth defects. Autoantibodies to hypothalamic vasopressin cells have been detected in some children previously thought to have idiopathic DI. Interestingly, about 50% of the patients who have histiocytosis also have vasopressin cell autoantibodies. In adolescents with acquired lymphocytic or granulomatous hypophysitis, hyperprolactinemia and

other anterior pituitary dysfunction may accompany the DI. The physician must search diligently for an underlying lesion that may not be evident at the initial evaluation.

### Nephrogenic Diabetes Insipidus

Renal disorders, both congenital and acquired, may be associated with polyuria because of a complete or partial inability of the renal tubule to concentrate urine despite normal or elevated circulating levels of vasopressin. Inherited forms of nephrogenic DI are rare, and symptoms of profound polyuria—vomiting, fever, failure to thrive, and hypernatremic dehydration—typically occur within the first weeks of life. Breastfed infants may show signs later than those who are bottle fed because of the lower osmotic load in human milk. The condition can be associated with damage to the CNS or even death if the infant develops recurrent hypernatremic dehydration. Older children and adults may be able to adjust their oral fluid intake to maintain serum osmolality. Mutations in the vasopressin V2 receptors of the distal convoluted tubule and collecting duct have been reported in affected members of kindreds with nephrogenic DI. A rare form of autosomal recessive nephrogenic DI has been described in patients with mutations in the gene for the water-channel protein aquaporin-2.

Besides the hereditary form of nephrogenic DI, the physician must consider other renal tubular defects in which vasopressin resistance has been observed. Patients who have cystinosis, distal renal tubular acidosis, renal Fanconi syndrome, or Bartter syndrome may have polyuria. An association between nephrogenic DI and the syndrome consisting of arthrogryposis, renal tubular dysfunction, and cholestasis (ARC syndrome) has been recognized; affected children are prone to severe growth impairment, as well as to intellectual disability and deafness. Structural abnormalities of the kidney leading to polyuria include congenital abnormalities such as renal dysplasia, familial juvenile nephronophthisis–medullary cystic disease, and oligomeganephronia, as well as acquired lesions caused by chronic pyelonephritis or obstructive uropathy.

In a systematic review of causes of nephrogenic DI, the most frequently reported risk factors for reversible vasopressin insensitivity were lithium, antibiotics, antifungals, antineoplastic agents, and antivirals. Longer duration of treatment with lithium correlated with increased risk for irreversible DI. Metabolic disturbances can also result in reversible vasopressin resistance. Hypercalcemia and hypokalemia each may be associated with a nephropathy in which tubular ability to conserve water is lost. Certain systemic disorders, such as sickle cell disease, sarcoidosis, and amyloidosis, also may cause renal tubular dysfunction and result in polyuria.

### Excess Water Intake

Polyuria is sometimes a consequence rather than a cause of excessive fluid intake. The ailment has a gradual onset, unlike the more abrupt onset typical of central DI. Primary polydipsia is a rare cause of polyuria in childhood. In primary polydipsia, excess fluid

intake can alter the renal medullary concentration gradient, leading to a relatively hypo-osmolar state. Primary polydipsia is diagnosed after excluding other possible causes of excessive water intake. However, as recently demonstrated in a child who was found to have a mutation in the *AVP* gene, an individual with evolving central DI can have a normal water deprivation test early in the disease course.

The term *psychogenic polydipsia* has been used to characterize excessive water drinking in institutionalized psychiatric patients and is most commonly associated with schizophrenia. Although some investigators believe this disorder is caused by a primary psychiatric disturbance, a study of adult patients with polydipsia and hyponatremia showed evidence of a defect in water excretion, osmoregulation of water intake, and vasopressin secretion. Although typical antipsychotic drugs such as haloperidol have been associated with worsening of polydipsia, clozapine has been reported to significantly reduce excessive water intake in limited studies.

### Osmotic Diuresis

Some patients have polyuria with renal water loss resulting from an osmotic diuresis. Glycosuria is frequently found to be the cause of sudden onset of polyuria in children with uncontrolled DM. In both type 1 and type 2 DM, diminished carbohydrate use results in hyperglycemia and glycosuria. When present in the urine at high concentrations, glucose acts as an osmotic diuretic, resulting in polyuria. Chronic hyperglycemia may also cause a form of partial nephrogenic DI. Osmotic diuresis may also be provoked by mannitol, radiologic contrast agents, or high-protein feedings (in which urea acts as the osmotic agent), or after the relief of bilateral urinary tract obstruction. Treatment with large volumes of dextrose-containing intravenous fluids can also result in hyperglycemia and polyuria. In contrast, renal glycosuria is characterized by a defect in renal tubular reabsorption of glucose, resulting in glycosuria without hyperglycemia or polyuria.
